ANNEXE A - VI - 1 : Les FONCTIONS de DISTRIBUTIONS

$$I -- INTRODUCTION [1], [2], [3], [4], [5]$$

Les temps de relaxation T_{1Z} , $T_{1\rho}$ en RMN, la permittivité diélectrique ε en relaxation diélectrique et la loi de diffusion neutronique $S(\vec{Q}, \omega)$ en IQNS sont des grandeurs physiques observables que nous noterons $M(\sigma)$ et qui dépendent du (des) temps de corrélation $\vec{\sigma}_{\alpha}$ caractérisant les mouvements moléculaires. Ceux-ci s'expriment généralement de façon simple en fonction des différents temps de résidence.

Nous ne considèrerons ici qu'un seul temps de corrélation (exemple du modèle de rotation diffusionnelle) dont la valeur peut être distribuée.

L'expérience donne accès à la grandeur M_{exp} qui tient compte de cette distribution. On peut écrire:

ou encore

Mexp	$= \int_0^\infty M(z) \cdot G(z) dz$	avec $\int_0^\infty G(c)$	$d\mathcal{Z} = 1 \left\{ \begin{array}{c} 1 & - a \\ a \end{array} \right\}$
M exp	$= \int_{-\infty}^{+\infty} M(z) F(z) dz$	avec $\int_{-\infty}^{+\infty} F(z) dz = 1$	$\begin{cases} 1 - t \\ \end{cases}$

et

 $z = Log(\mathcal{Z}/\mathcal{Z}_m)$ où \mathcal{Z}_m est le temps de corrélation pour lequel F(z) est maximale.

Les caractéristiques des fonctions G(Z) (linéaires) et F(z) (logarithmiques) doivent permettre de rendre compte d'une distribution continue des temps de résidence associés à un mouvement moléculaire.

L'introduction de cette distribution peut être physiquement justifiée en admettant que la dynamique de ce mouvement varie d'une molécule à l'autre parce que leur environnement local est différent.

II -- LES FONCTIONS DE DISTRIBUTION

Nous appellerons FWHM la largeur totale relative à mi hauteur de la distribution et $\langle \mathcal{G} \rangle$ le temps de corrélation moyen.

2

A) Distribution gaussienne(symétrique)

G (3) = $(\propto \sqrt{2\pi})^{-1} \exp(-(5 - \zeta_m)^2 / 2 \propto^2)$ FWHM = 2.35 \propto /ζ_m et $\langle \overline{c} \rangle = \zeta_m$ $\propto = 0$ pas de distribution

B) Log – gaussienne

 $F(z) = (\alpha' \sqrt{2\pi})^{-1} \exp(-z^2 / 2\alpha'^2)$

FWHM = 2 sinh ($\sqrt[\alpha]{2Log(2)}$) et $\langle \zeta \rangle = \mathcal{E}_{m} \exp(\langle \chi'^{2}/2 \rangle)$ $\langle \chi' = 0$ pas de distribution

<u>}</u>

C) Distribution de COLE et COLE (symétrique) [3]

$$F(z) = \frac{1}{2 \pi} \frac{\sin \pi}{\cosh (\gamma z) + \cos \gamma \pi}$$

FWHM = $2 \sinh \left[\gamma^{-1} \operatorname{Arg} \cosh \left(2 + \cos \delta \eta \right) \right]$ $\gamma = 1 \text{ pas de distribution}$

D) Distribution de FUOSS et KIRKWOOD (symétrique) [4]

E) Distribution de COLE et DAVIDSON (asymétrique) [5] $\begin{cases}
F(z) = \frac{\sin \delta \pi}{\pi} (e^{-z} - 1)^{\delta} & (z < 0) \\
F(z) = 0 & \text{pour } z > 0 \\
\delta = 1 \text{ pas de distribution}
\end{cases}$

III -- INTRODUCTION DES FONCTIONS DE DISTRIBUTION POUR L'INTERPRETATION DES RESUL-TATS EXPERIMENTAUX

Pour le modèle de diffusion rotationnelle isotrope ou celui de Frenkel les grandeurs physiques observables M(\mathcal{G}) ou M(z) sont des combinaisons linéaires de fonctions lorentziennes en RMN, en IQNS ou en relaxation diélectrique (\mathcal{E} ").

Pour cette technique, \mathcal{E}' s'exprime en fonction de $1/(1+\omega^2 \sigma_m^2)$.

Dans les deux cas, il est possible de trouver une expression analytique des expressions 1 - a ou 1 - b permettant ainsi un calcul simple de M_{exp} [2]

A) En RMN

AMOUREUX et SAHOUR [1] cherchent à expliquer la dissymétrie de la courbe $T_{1Z} = f(10^3/T(K))$. Ils montrent que les distributions de COLE et COLE, de FUOSS et KIRKWOOD et de COLE et DAVIDSON rendent compte de cette anomalie et que la position du minimum de T_{1Z} n'est pas affectée par les distributions.

B) En relaxation diélectrique

La permittivité complexe calculée en introduisant les fonctions de

distribution de COLE et COLE (CC) ou de COLE et DAVIDSON (CD) a déjà été décrite en[VI - 35]et[VI - 36].

AMOUREUX et SAHOUR [1] montrent que si la distribution est symétrique, sa largeur n'influe pas sur la fréquence critique F_C , ce qui n'est pas le cas pour une distribution asymétrique. De plus, l'énergie d'activation mesurée en relaxation diélectrique est indépendante de l'existence d'une distribution symétrique. Pour une distribution asymétrique, l'énergie d'activation est différente mais sa variation est moins importante en relaxation diélectrique qu'en RMN.

C) IQNS [6]

Nous avons étudié l'influence de la distribution de FUOSS-KIRKWOOD sur la loi de diffusion théorique $S(\vec{q}, \omega)$. Soit S_{exp}^{D} (\vec{q}, ω) la loi de diffusion expérimentale tirée de VII-28. Les caractéristiques de S_{exp}^{D} (\vec{q}, ω) ont été étudiées dans le cas du modèle de rotation uniaxiale d'ordre 12 en tenant compte de la résolution instrumentale. On trouvera le détail du calcul dans l'annexe A-XI-5.

L'introduction de cette distribution permet de rendre compte de l'excès de diffusion élastique observé dans le cas du CNADM. On montre également que l'interprétation d'un spectre expérimental distribué par un modèle à un seul temps de résidence conduit à la surestimation de ce temps.

Finalement, on trouve que cet effet devient faible si la largeur (FWHM) de la première lorentzienne du modèle est au moins 3 fois supérieure à celle de la résolution instrumentale.

ANNEXE A - VI - 2 :

RELATIONS entre les TEMPS de CORRELATION et les TEMPS de RESIDENCE en RMN

Pour le modèle de Frenkel et dans le cas où la molécule effectue une rotation autour de son axe ainsi qu'un basculement par rapport aux axes cristallins, la fonction d'autocorrélation est décrite par une somme de 6 exponentielles dont les temps de corrélation sont notés $\Im \alpha$. Ceux-ci sont liés aux temps de résidence \Im_{mp} et \Im_{CG} par les expressions suivantes :

G-1 1	=	ς-1 b1		
۲ کے 2	=	ъ-1 b1	+	了 <mark>-1</mark> r1
Z ^{−1} 3	=	ሪ <mark>-1</mark> b1	+	て ⁻¹ r2
5 <mark>-1</mark> 4	- =	ჳ <mark>-1</mark> ხ2		
5 <mark>-</mark> 1 5	=	ჳ <mark>-1</mark> ხ2	+	5 <mark>-1</mark> 1
5 <mark>-1</mark> 6	=	G ⁻¹ b2	+	τ ⁻¹ r2

où \mathcal{C}_{b1} , \mathcal{C}_{b2} , \mathcal{C}_{r1} , et \mathcal{C}_{r2} s'expriment à partir des temps de résidence des mouvements de basculement et de rotation uniaxiale d'ordre p respectivement.

$$\begin{aligned} \mathbf{c}_{b1}^{-1} &= \frac{4}{3} \mathbf{c}_{c4}^{-1} + \frac{2}{3} \mathbf{c}_{c2}^{-1} + \mathbf{c}_{c3}^{-1} + \frac{4}{3} \mathbf{c}_{c2}^{-1} \\ \mathbf{c}_{b2}^{-1} &= \mathbf{c}_{c4}^{-1} + \mathbf{c}_{c2}^{-1} + \frac{3}{2} \mathbf{c}_{c3}^{-1} \\ \mathbf{c}_{b2}^{-1} &= \frac{(2-\sqrt{3})}{2} \mathbf{c}_{m12}^{-1} + \frac{1}{2} \mathbf{c}_{m6}^{-1} + \mathbf{c}_{m4}^{-1} + \frac{3}{2} \mathbf{c}_{m3}^{-1} + 2\mathbf{c}_{m2}^{-1} \\ \mathbf{c}_{r1}^{-1} &= \frac{(2-\sqrt{3})}{2} \mathbf{c}_{m12}^{-1} + \frac{3}{2} \mathbf{c}_{m6}^{-1} + 2\mathbf{c}_{m4}^{-1} + \frac{3}{2} \mathbf{c}_{m3}^{-1} + \mathbf{c}_{m2}^{-1} \\ \mathbf{c}_{r2}^{-1} &= \frac{1}{2} \mathbf{c}_{m12}^{-1} + \frac{3}{2} \mathbf{c}_{m6}^{-1} + 2\mathbf{c}_{m4}^{-1} + \frac{3}{2} \mathbf{c}_{m3}^{-1} + \mathbf{c}_{m2}^{-1} \end{aligned}$$

de façon générale :

$$\mathcal{Z}_{rq}^{-1} = 2 \sum_{p} \frac{\sin^2 (\pi_q/p)}{\zeta_{mp}}$$

Pour un échantillon de poudre, les vitesses de relaxation deviennent:

$$T_{1Z}^{-1} = \frac{2}{3} \Delta M_2 \sum_{\alpha=1}^{6} \Psi_{\alpha} \Big[L(\omega_0, \zeta_{\alpha}) + 4L(2\omega_0, \zeta_{\alpha}) \Big]$$

$$T_{1P}^{-1} = \frac{2}{3} \Delta M_2 \sum_{\alpha=1}^{6} \Psi_{\alpha} \Big[\frac{3}{2} L(2\omega_1, \zeta_{\alpha}) + \frac{5}{2} L(\omega_0, \zeta_{\alpha}) + L(2\omega_0, \zeta_{\alpha}) \Big]$$

$$avec_{\alpha} \sum_{i=1}^{6} \Psi_{\alpha} = 1 \quad et \quad \Psi_{\alpha} = \frac{k \neq 1}{k \neq 1} \frac{A_{k1,\alpha}^m / r_{k1}^6}{k \neq 1 - r_{k1}^{-6}}$$

CHAPITRE VIII

ANNEXE

CHAPITRE VIII

ANNEXE
$$A - VIII - 1$$

1) FORMULATION GENERALE

Pour les librations isotropes, \mathcal{G}_{μ}^{HC} (A) et \mathcal{G}_{μ}^{FR} (A) ont la même symétrie et deviennent identiques :

$$\sum_{\text{lmm}} A_{\text{mm}}^{1}, M_{\text{m}}^{1}, (\Omega_{\text{M}}^{\mu}) K_{\text{m}}^{1} (\Omega) = \frac{1}{2\pi NL} \sum_{j=1}^{N} \exp\left(-\frac{\Theta_{\mu j}^{2}}{2L}\right) \quad \left[A-1\right]$$

 $-\Omega_{M}^{\mu}$ = angles polaires définissant l'atome μ dans la molécule.

- N = nombre de positions d'équilibre
- $\theta_{\mu j}$ = angle de libration de l'atomeµ dans la j^{ième} position d'équilibre.
- L = (Li pour ADM ou L pour l'axe Δ de FADM) est l'amplitude quadratique moyenne de libration.

Les propriétés d'orthonormalisation des fonctions K_m^1 conduisent à :

$$\sum_{m'} A_{mm}^{1}, M_{m'}^{1}, (\underline{\Omega}_{M}^{\mu}) = \frac{1}{2\pi NL} \sum_{j=1}^{N} \int \exp\left(-\frac{\vartheta_{\mu j}^{2}}{2L}\right) K_{m}^{1} (\underline{\Omega}) d\Omega \left[A - 2\right]$$

Les positions d'équilibre et les fonctions K_m^1 suivent la symétrie cubique. La valeur de l'intégrale dans [A - 2] est identique pour toutes les orientations j, d'où :

$$\sum_{m'} A_{mm}^{1}, M_{m}^{1}, (\Omega_{M}^{\mu}) = \frac{1}{2 \Pi L} \int \exp\left(-\frac{\Theta'_{\mu}^{2}}{2 L}\right) K_{m}^{1}(\Omega) d\Omega \quad \left[A-3\right]$$

II) MOLECULE FIXE : LIBRATION NULLE

Lorsque la molécule est fixe, l'atome est fixé par ses angles polaires dans le réseau (Ω_R^μ).

Dans ce cas, les coefficients A_{mm}^{1} , (f) (f pour molécule fixe) sont donnés par :

$$\sum_{m'} A_{mm}^{1}, (f) M_{m'}^{1}, (\Omega_{M}^{\mu}) = K_{m}^{1} (\Omega_{R}^{\mu}) \qquad [A - 4]$$

Pour une symétrie moléculaire T_d ou $O_h \left[A - 4 \right]$ devient :

$$\sum_{m'} A_{mm}^{1}, (f) K_{m'}^{1}, (\Omega_{M}^{\mu}) = K_{m}^{1} (\Omega_{R}^{\mu}) \qquad [A - 5]$$

Cette relation se simplifie encore si les positions d'équilibre ont la symétrie du site ($\Omega_M^\mu = \Omega_R^\mu$).

$$\hat{A}_{mm}^{1}$$
 (f) = $\int mm'$ [A - 6]

Pour l'axe $C_3(\Delta)$ de FADM, les coefficients \hat{A}_{mm}^1 , non nuls sont tels que m' = 1, et on trouve :

$$\hat{A}_{m1}^{1} (f) = \sqrt{\frac{4\pi}{21+1}} K_{m}^{1} (\Omega_{R}^{\Delta}) \qquad [A - 7]$$

III) MOLECULES EFFECTUANT DES LIBRATIONS

Pour ADM, on obtient simplement les coefficients A_{mm}^1 à partir de A - 3 :

$$\widehat{A}_{mm}^{1} = \frac{1}{2\Pi L_{i} K_{m}^{1}} \int \exp\left(-\frac{\Theta_{\mu}^{2}}{2L_{i}}\right) K_{m}^{1}(\Omega) d\Omega \qquad [A-8]$$

De même, les termes \hat{A}_{m1}^{1} décrivant l'orientation de l'axe Δ de FADM s'écrivent :

$$\hat{\hat{A}}_{m1}^{1} = \frac{1}{2\pi L_{\perp}} \sqrt{\frac{4\pi}{21+1}} \int_{\Omega} \exp(-\frac{\theta'^{2}}{2L_{\perp}}) K_{m}^{1} (\Omega) d\Omega \qquad [A - 9]$$

Dans les deux cas, les rapports A^1/A^1 (f) sont donnés par [A - 8]. Ils ne dépendent que des positions d'équilibre dans le réseau cubique de l'atome μ (ADM) ou de l'axe Δ (FADM).

L'équation [A - 8] a été programmée pour différentes valeurs de L et pour les orientations < 001>, < 110> et< 111>. Les courbes tracées sur la figure IX - 5 représentent les variations des coefficients A_{mm}^1 , pour les ordres 4 à 12. Seuls les coefficients d'ordre 10 dépendent de l'orientation considérée et pour des angles de libration importants (>7°).

ANNEXE A-XI-1

Abstract. In this Letter we present experimental results which show the existence of a 'glassy crystal' phase obtained by the quenching of the 1-cyanoad.mantane plastic phase. From the DSC data, the glass transition temperature has been obtained and the glassy crystalline 1-cyanoadamantane has been shown to relax during annealing at 160 K. The 'glassy crystal' is cubic (FCC) and is characterised by the vanishing of some low -frequency Raman contributions of the plastic phase.

Adachi et al (1968) have demonstrated the possible existence of glasses of a new kind obtained from the quenching of some molecular crystals initially in their disordered rotator phase (plastic crystals). If the crystal is cooled rapidly enough to prevent the transition towards the low-temperature ordered phase, the disordered system is supercooled and ultimately goes into a glassy state. On gradual reheating it passes through a 'glass transition' at which the glassy form transforms irreversibly into the low-temperature metastable form of the plastic phase. In the glassy phase, the average translational order of the plastic phase is preserved but the orientational disorder would be frozen. These features have led Seki to propose the apparently paradoxical term 'glassy crystal' for this new condensed state of matter (Adachi et al 1968), which is particularly attractive because the transition to the glassy state could be selectively observed on the molecular orientations. Up to now these phenomena have been mainly studied on the particular cyclohexanol (Adachi et al 1968, James et al 1976, Ceccaldi et al 1980). In the present Letter, we report the results of preliminary experiments on cyanoadamantane (CN-ADM) whose plastic phase can be easily supercooled even when operating with single crystals. These experiments are DSC, x-ray diffraction and Raman scattering. The molecule exhibits only one conformation and the crystal structure in both the plastic and ordered low temperature phase has been solved (Amoureux eral 1981a). The plastic phase has an FCC structure with four molecules in the cubic cell and no long-range order of the molecular orientations. The dipolar axis can randomly take six orientations very closely located along the (001) directions. The corresponding reorientations are slow with correlation times of about  $r_{r} = 3 \times 10^{-7}$  s at room temperature. On the other hand, reorientation processes have been detected (Amoureux ct al 1981b and references therein) in higher frequencies which correspond to fast uniaxial rotations around the dipolar axis. An elementary analysis of figure 1 shows that the sterical repulsions between molecules are a predominant feature of the interactions (Descamps 1982).

Figure 1. Example of suitable packing in the (001) plane.

DSC curves under various cooling and heating conditions were obtained using a Perkin-Elmer differential scanning calorimeter, the sample being scaled into aluminium calorimetric cells. CN-ADM is in the plastic phase (1) at room temperature and it is easily quenched when cooling more rapidly than -1.5 K min⁻¹. After the crystal is supercooled, the reheating behaviour is of the type shown in figure 2. In this case, the crystal I was supercooled to about 100 K with a cooling rate of -1.5 K min⁻¹ and the heating rate was 40 K min⁻¹. The successive events of the curve can be interpreted as follows:

(i) The endothermic anomaly at about 170 K is due to a glass transition from the glassy crystalline phase (1,) to the metastable phase (1').

(ii) The exothermic irreversible transition at about T = 205 K corresponds to the transition from the metastable form (1') to the low-temperature monoclinic phase (11).

20

8

(iii) The endothermic peak at T = 283 K is the usual non-plastic-plastic transition.

The melting occurs at higher temperature  $(T_m \simeq 458 \text{ K})$ . Figure 3 gives more detailed results of calorimetric measurements in the  $T_g$  zone after two different thermal treatments.

Curve A: sample quenched from 295 K to 100 K with a cooling rate of -1.5 K min⁻¹, annealed at 160 K and heated with a rate of 40 K min⁻¹: the heat capacity starts to increase rapidly at about 165 K which may define the glass transition temperature  $T_{ij}$ ; then it passes through a high maximum at approximately 130 K. The narrow cusp is followed by the plateau of the metastable phase which extends on 20°. The height of the peak measured above the plateau is larger than the final heat capacity jump.

Curve B: sample quenched from 295 K to 77 K in a few seconds and immediately heated with a rate of 40 K min⁻¹: the heat capacity curve shows a minimum at about 160 K before increasing and the cusp is much less sharp than in curve A.

The difference between these two curves obtained after different thermal treatments can probably be looked upon as a relaxation phenomenon associated with the glass transition, as has been observed in the cyclohexanol case (Adachi et al 1968).

Since crystals of the plastic phase with dimensions suitable for x-ray diffraction and Raman scattering were grown by evaporation and sublimation respectively. CN-ADM is not hygroscopic and sublimes slowly so it can be worked without any protection. Both crystals could be quenched and ultimately gave rise to a single-crystal of the glassy phase. X-ray data collections have been recorded from the same single crystal: (a) in the

X-ray data collections have been recorded from the same single crystal: (a) in the plastic phase, T = 295 K; (b) in the glassy phase, T = 110 K. In the second case, the monocrystalline sample has been rapidly quenched from 295 K to 110 K in a few seconds. All the diffraction intensities increase in the glassy phase and the number of significant independent Bragg peaks ( $F_0/\sigma \ge 3$ ) goes from 42 in the plastic phase to 84 in the glassy phase. In both cases, the lattice is FCC (Z = 4) with cubic parameters: a = 9.813 Å at 225 K and a = 9.638 Å at 110 K.

The Raman measurements were performed using a 'Corterg T 800' spectrometer with incident radiation ( $\lambda = 4880$  Å) of 100 mW at the sample and constant energy slit

### Letter to the Editor

width of  $2 \text{ cm}^{-1}$ . The glassy phase was obtained by quenching the crystal to 140 K in few seconds.

The profiles of the Raman spectra in the plastic and glassy phases are shown in figure 4. An important change in the shape of the low-frequency Raman spectrum is observed. This change appears more strongly in the profile of the renormalised spectra obtained from the experimental Stokes spectrum  $S(\nu)$  by the usual transformation

### $S'(\nu) = \nu S(\nu)/(n(\nu) + 1)$

where n(v) + 1 is the thermal population of the initial states.

The maximum of the  $S'(\nu)$  spectrum occurs at  $\nu_m = 56 \text{ cm}^{-1} (\pm 2 \text{ cm}^{-1})$  in the two phases. However,  $S'(\nu)$  is a symmetric function in the glassy phase (line width  $\Gamma_G = 35 \text{ cm}^{-1} (\pm 3 \text{ cm}^{-1})$ , FWHM). This band is asymmetric in the plastic phase because additional contributions are Raman active in a low-frequency range ( $\nu < 40 \text{ cm}^{-1}$ ). In a disordered phase, the shape of the low-frequency Raman spectrum is connected to the envelope of the whole libron frequencies allowed by the different local neighbourings of molecules and the breakdown of the q selection rule (Sauvajol *et al* 1982). The vanishing of the low-frequency contributions in a Raman spectrum of a glassy phase suggests that some order sets in the system and several modes become inactive in the glassy phase.

On the other hand, at a temperature T just above  $T_4$ , a spontaneous evolution of the Raman spectrum, from the one of the glassy state to one of low temperature, is observed (figure 5).

All the results presented in this Letter can be coherently interpreted through the possible occurrence of a glassy crystal phase for the CN-ADM with  $T_s = 170$  K. Operating with powder, this phase can be easily obtained by quenching the plastic phase with a cooling rate as slow as 1.5 K min⁻¹ and the thermal comportment under reheating appeared extremely sensitive to an annealing. The monocrystalline sample of the glassy phase obtained by quenching it in a few seconds is cubic FCC and the vanishing of the low-frequency contribution ( $\nu < 40$  cm⁻¹) is the Raman 'signature' of the glassy state. Experiments are actually done to study the local order in this phase; on the other hand, dielectric experiments are performed in order to observe how the slowing down of the dipolar reorientation is implicated in the glassy transition and if it follows a Vogel-Fülcher law.

The authors would like to acknowledge M Muller and C Carpentier for growing the crystals; Dr J P Cavrot for his help during DSC experiments and Dr H Szware and R Vacher for kind discussions. We wish to thank A Hüller and W Press for their reading of the manuscript.

difference of heat capacity between the I_s and I' phases is observed:  $\Delta C_s = (16.0 \pm 1.3)$ . J mol⁻¹ K⁻¹. The structure of the ordered phase is analysed at two temperatures: 138 and 240 K. The space group is  $C_2/m$  with Z = 4 and  $A_m = 11.278$  Å,  $B_m = 6.374$  Å,  $C_m =$ Abstract. All the different crystalline (brittle (II), glassy (1,), plastic stable (1) and metastable (l')) phases of 1-cyanoadamantane: CuHisCN are characterised by differential scanning calorimetry studies. The transition temperatures and their respective enthalpies are determined: 1,-1' (170 K), 11-1 (250 K, 5.5 kJ mol-1), 1-11quid (153 K, 15 kJ mol-1). A 12.092 Å and p = 101" 37' (at 240 K).

In this ordered phase the antiparallel order of the dipole moments is puinted out. From the positions of the molecular mass centres, a pseudo-cubic lattice is built which tends to the cubic plastic lattice at the transition  $\mathbf{I} - \mathbf{I}$ . The orientations of the dipolar axes are compared with those found in the plastic phase. The longitudinal relaxation time  $T_{iz}$  in ¹H-NiR gives corresponding ones ubrained with diefection relaxation and incohercent neutron diffusion. In the glassy state a change in the uniaxial foration occurs which may be anributed to a large us a very good description with temperature of the molecular motions in all the different crystalline phases. The residence times deduced from this NMR, such agree very well with the distribution of residence times.

**I.** Introduction

ena arises from the tact that usual glasses are composed of deformable components obtained from the quenching of some molecular plastic crystals, has recently been shown The usual glasses (obtained from the quenching of a liquid) have been currently used for several thousands of years (SiO₂) and nowadays their macroscopic properties are very well characterised but in an empirical way. Indeed the microscopic description of this glassy state is still unknown in spite of the numerous studies pursued in laboratories all over the world. The main reason for this lack of knowledge of the microscopic phenomsituated in an embedding without long-range order. Therefore most experiments can only bring averaged information corresponding to the macroscopic properties. Fortu-(Adachi er al 1968). When the crystal in its rotator phase is cooled rapidly enough to prevent the transition towards the low-temperature ordered phase, the disordered system is supercooled and ultimately goes into a glassy state. In this glassy phase the nately the existence of glasses (from the thermodynamic point of view) of a new kind,

 $\sim$ - I X - V ANNEXE

Figure 1. The molecule of cyanoadamantane, carbon atoms are in white, hydrogen in black and nitrogen is dashed. A cube has been drawn to indicate the directions of atoms with respect to each other; it does not correspond to the directions of the unit cell.

average translational order of the plastic phase is preserved but the orientational disorder is partially frozen. These features have led to the apparently paradoxical term 'glassy crystal' for this new condensed state of matter which is particularly attractive because the transition to the glassy state can only influence the molecular orientations. In the present paper, we report the results of some experiments on 1-cyanoadamantane whose plastic phase can easily be supercooled even when operating with single crystals. These experimental results (DSC, x-ray diffraction and NMR) can be coherently interpreted through the occurrence of a glassy state which enables us to put forward some hypothesis on the microscopic description of the glassy state. 1-cyanoadamantane (CN-ADM):  $C_{10}H_{15}CN$ , formally known as 1-cyano tricyclo[3,3,1,1] decane is composed of rigid globular molecules. It can be obtained from adamantane C10H16 by substituting a cyano group onto a methine carbon (figure 1). This long cigar-shaped substituent gives a large permanent dipole moment ( $u_{x} = 3.83 \text{ D}$ ) to the molecule which is in a plastic phase at room temperature (melting point:  $T_m = 458$  K). Microwave spectra (Chadwick et al 1972) and ¹³C chemical shift (Krishnamurthy er al 1983) have shown that this substitution does not change the rest of the molecule whose symmetry is then C_{1v}.

### 2. Differential scanning calorimetry (osc) studies

### 2.1. Experimental conditions

DSC curves under various cooling and heating conditions were obtained using a Perkin-Elmer differential scanning calorimeter DSC II. The powder samples sealed into aluminium calorimetric cells weighed between 20 and 27 mg. According to the experiments the cooling rate varied from 1.5 to 320 K min⁻⁴ The displayed cooling rates and the real ones were always identical at least above 160 K. The DSC II calorimeter was

4215

calibrated with indium  $(T_m = 429.55 \text{ K}, \Delta H_m = 28.42 \text{ Jg}^{-1})$  and with succinonitril,  $(CH_2 - C \equiv N)_2$   $(T_i = 233 \text{ K}, \Delta H_i = 26.54 \text{ Jg}^{-1})$ . The transition temperatures at the peaks were always deduced from the extrapolated onset from the base line.

### 2.2. Description of the various solid phases

All the studies carried out with different techniques have shown that cyanoadamantane exists in four different solid states: a stable plastic phase (I), a supercooled metastable plastic phase (I'), a glassy state ( $I_4$ ) and an ordered phase (II).

It is certainly possible to obtain another glassy state from the quenching of the liquid phase. However up to now this 'usual' glassy state has not been really seen yet.

If the sample of CN-ADM is cooled rapidly enough, the thermodynamic behaviour, when the temperature is increased, is of the type shown in figure 2. In this case, the sample was warmed at  $\pm 40$  K min⁻¹ from 100 K to 300 K after a very long annealing just below the glass transition.

Figure 2. DSC curve obtained during the reheating process ( $\approx$  40 K min⁻¹), corresponding to a quenching followed by a long annealing.

The successive features of this curve can be interpreted as follows:

(i) The endothermic anomaly at  $T_s \approx 170$  K is due to the glass transition from the glassy state  $I_s$  to the metastable plastic phase I'. Whatever the cooling or heating rates are, this glassy transition is always observed at approximately the same temperature:  $T_s = (170 \pm 3)$  K. In 'usual' glasses the important internal molecular deformations and the numerous translational diffusion (large vacancy concentration) are perhaps related to the fact that in these compounds,  $T_t$  is strongly dependent on the thermal treatments. In CN-ADM, internal deformations and translational diffusion in the solid state (\$5) do not exist and in the glassy state there still remains only one degree of freedom. In figure

2, one can see that there exists a difference of heat capacity ( $\Delta C_{\mu}$ ) between the glassy (1,) and the supercooled (1') phases. From this DSC curve we have obtained a value of  $\Delta C_{\mu}$  which has recently been confirmed by other calorimetric experiments (Bonjour and Calemczuk 1983, Fuchs 1983):

$$\Delta C_{a} = (16.0 \pm 1.3) \, \text{J mol}^{-1} \, \text{K}^{-1}$$

(ii) The exothermic irreversible transition at about 205 K corresponds to the transition from the metastable form to the low-temperature ordered phase  $[1' \rightarrow II]$  known as 'recrystallisation'. As usually observed in many plastic crystals, there can occur a noticeable delay in the transformation from the disordered phase to the ordered one  $[1' \rightarrow II]$ . This delay is more or less important according to the crystals and therefore this transition runs over 50 K in this powder sample.

(iii) The endothermic peak at  $T_i = 280$  K is the usual brittle-plastic transition ( $[II \rightarrow I]$ ). The ratio  $T_i/T_i$  which is equal to 0.6 for CN-ADM is included between 0.5 and 0.7 as in all glasses. When the temperature is slowly decreased from 300 K, there always exists a very important delay in this transition (>30 K).

(iv) The endothermic peak corresponding to the melting point  $(T_m = 458 \text{ K})$  is not shown in figure 2.

Figure 3. Polymorphic forms and thermal properties of CN-ADM.

We have measured in an accurate way the transition enthalpy change at 280 K:  $\Delta H_i = (5.5 \pm 0.2)$  kJ mol⁻¹. The fusion enthalpy change was not measured with a good precision because CN-ADM sublimates at high temperatures and the calorimeter cells were not perfectly scaled. However by measuring the weight of the cells before and after each experiment, we have obtained an estimation of this fusion enthalpy change:  $\Delta H_m = (15 \pm 3)$  kJ mol⁻¹. Contrary to most plastic crystals,  $\Delta H_m$ , is considerably lower than  $\Delta H_m$ . This small value of  $\Delta H_i$  is perhaps related to the inct that in all the plastic

A glassy crystal: I-cyanoadamantane

phase the disorder of the cyano group can be considered as quasi-static (Amoureux *et al* 1984) which is not the case for other plastic crystals.

# 2.3. The recrystallisation $(l' \rightarrow ll)$

When the sample is rapidly quenched (-320 K min⁻¹) from 300 K to 100 K, all the CN-ADM passes into the glassy state and then the enthalpy change of the recrystallistationis identical to that of the transition at 280 K. With different cooling rates, measuring the recrystallisation enthalpy change during the reheating process allows a determination of the proportion,  $\delta$ , of CN-ADM that has recrystallisation when a powder sample is cooled faster than 120 K min⁻¹. However it is very important to specify that this behaviour is strongly related to the purity of the product. In our experiments we have always used examples to the purity of the product. In our experiments we have always used examples to the purity of the product.

We have observed the swiftness of this recrystallisation in another way. The sample was cooled very rapidly (-320 K min⁻¹) from 300 K down to a temperature *T* higher than  $T_4$ , where it was maintained for a time *t*. The temperature was then increased very quickly. The area of the transition peak at 280 K indicates the proportion,  $\delta$ , of CN-ADM that has recrystallised (table 1).

Table 1. Proportion 5 of CN-ADM which has recrystallised after waiting t minutes at temperature T.

M Foulon et al 4218 When a single crystal is quenched, its behaviour is quite different from that observed with powder: this single crystal passes nearly completely either into the glassy phase or into the ordered phase.

# 2.4. The glassy transition

is maintained for a time t at T. The temperature is then decreased to 90 K and finally the quenched very quickly from 300 K down to a temperature T just below  $T_{\rm k}$ . The sample In order to study specifically the glassy transition it is necessary to use very fast cooling rates (-320 K min⁻¹) to prevent recrystallisation, and fast heating rates (40 or 80 K min⁻¹) to enhance the output signal. To carry out an annealing the sample is first curve obtained when reheating from 90 K to 300 K is analogous to that of figure 2.

transition for different thermal treatments: ---- the sample was put directly into liquid aitrogen; ---- annealing for 10 min at 160 K; ---- annealing for 2 h at 160 K. These three Figure 5. DSC curves obtained during the reheating process (+40 K min -1) around the glassy curves correspond to three different samples and are in arbitrary units

exothermic surface (figure 5) at about 160 K and it does not exhibit a plateau in the metastable (1') phase. When the quenching has been followed by an annealing, the DSC curve is composed of a more or less pronounced plateau preceded by a maximum: 'the Moreover the small exothermic area at about 160 K is no longer observed, which cusp'. When the annealing time tincreases, the plateau extends and the 'cusp' grows up. If the quenching has not been followed by an annealing, the DSC curve shows a small indicates that a relaxation phenomenon occurs during this annealing.

order, described by a correlation length. Therefore one can think that, during the sively. Obviously, the possible relationship between the local orders in the glassy state Very recently (Descamps et al 1983), Raman, x-ray and coherent neutron diffusion experiments have shown that the glassy state is characterised by an important local anneating, this local order is setting in with the correlation length increasing progresand in the ordered phase (II) is of hirst unportance.

A glassy crystal: 1-cyanoadamantane

Knowledge of the structures of cyanoadamantane in all its phases, whether ordered or not, is therefore necessary.

# 3. Structure of the ordered phase

The analysis of the structure by x-ray diffraction gives the equilibrium positions of the molecules, their arrangement in the crystal and their thermal motions which permits a comparison of the long-range order in the different phases.

# 3.1. Crystallisation and diffraction study

As described above, using a single crystal grown at room temperature, phase II is accessible either by slow cooling or by quenching in the glassy state followed by a reheating. In both cases, the crystal becomes polycrystalline, because 3f an important first-order transition, and cannot be used for further x-ray diffraction studies.

The crystal was therefore grown directly in phase II under  $T_i$  at 253 K, by evaporation of a saturated solution in methanol. The crystallisation, the choice of the crystal and its setting up on the goniometer head were carried out in an adapted freezer. The crystal protected from thermal accident was transferred on a PW1100 four-circle diffractometer at 253 K. The 'peak hunting' of 25 reflections revealed that the crystal was constituted of two single crystals widely disorientated.

of about 120° along an axis which is perpendicular to their (a, b) planes. This leads to the it becomes obvious that the crystal belongs to the monoclinic system with  $C_3/m$  space The measurement of some integrated intensities indicated that one part represents 80% of the whole volume. The two direct lattices correspond to each other by rotation group. The diffracted intensities are corrected by the Lorentz polarisation factor but After correction of this effect and selection of the biggest crystal in the data collection, superposition of some reciprocal lattice points {{hh/h, with {hh/h, and {hh/h}, with {hh/h},

not for the absorption ( $\mu_i = 0.733$  cm⁻¹). Two sets of intensities were collected at 138 K and 240 K. The crystallographic parameters are represented in table 2. The temperature was then increased up from 108 K to T, (280 K  $\pm$  3 K). The lattice parameters were determined at various temperatures during the reheating (figure 6). They do not vary linearly with temperature and only |b| decreases when the temperature increases.

# 3.2. Resolution and refinement of the structure

All the 'heavy' atoms were located using the MULTAN Program (Germain *et al* 1971). The hydrogen atoms were found later by successive difference Fourier maps. There are four molecules in the unit cell and eight symmetry operations. A molecular symmetry plane coincides with the space group plane m. The structure was refined according to two different models of atom coordinates and thermal motions:

(i) independent atoms and anisotropic temperature factors using the SHELX program (Sheldrick 1976);

(ii) a rigid molecular group and its TLS (Shomaker and Truebload 1968) adapted description of thermal motion using the ORION program (André et al 1971).

The TLS tensors are also deduced from (i) by least-squares refinement using the TLS program (Shomaker and Trueblood 1963). The comparison between these tensors in procedures (i) and (ii) enables the validity of the rigid group assumption to be evaluated. These different refinement processes converge quickly and the conventional *R* factors (about 0.04) (table 2) measures the good agreement between the models and the

real structure  $\hat{r}$ . A last refinement, suppressing the space group  $r^{1}$  ine m. (space group  $r^{2}$  in  $r^{2}$  is a some parameters and the observed and calculated structure factors are available on request from Dr M Foulon.

C2) leads to the same results. The position and orientation of the molecule do not change significantly. A last difference Fourier map exhibits no abnormal residual electronic density.

# 3.3. Molecular geometry and packing

The intramolecular bond distances and angles agree well with those found in the literature (Chadwick *et al* 1972). The fractional coordinates of the molecular centre of muss are X/a = 0.2462, Y/b = 0.0, Z/c = 0.2310, near ( $\frac{1}{4}$ , 0,  $\frac{1}{4}$ ). The threefold molecular axes always lie in planes parallel to the crystallographic ones (a, c) at Y/b = 0 and  $\frac{1}{4}$ . The angle between these axes and the a base vector is 98° 8′ (Mod 180°) at 240 K.

Figure 7. Perspective view of the molecular packing in a direction nearly parallel to the  ${\cal U}_{ij}$  axis.

The structure may be described by a succession of parallel planes of molecules. In such a planar lattice, the pattern is constituted by two molecules related by a symmetry centre (molecules I and 2 in figure 7). The antiparallel directions of the dipolar moments lead to an antiferroelectric order. The distances between the atoms of a molecule and those of the neighbouring ones are always greater than the sum of the corresponding Van der Waals radii. Two next-neighbour molecules do not form a dimer in this lowtemperature phase. Thus, the steric hindrance is weak when the molecules stay at their equilibrium positions.

The NMR experiments and their interpretation reported below point out that a molecular motion subsists in phase II. According to the single discernible equilibrium position of the molecule in its site, this motion can only be described as a threefold uniaxial rotation along the  $C--C \equiv N$  group.

The calculation of the interatomic distances between a uni-stally rotating molecule and its neighbourhood shows a large steric hindrance during this rotation. Its mechanism
4222 M Foulon et al

is certainly complicated and may involve a correlated motion of the molecules and (or) a deformation of the  $C-C\equiv N$  group.

## 3.4. Analysis of the thermal motion

The TLS tensors deduced from the two refinement models are identical (table 3). It proves that the whole molecule may be considered as a rigid group. The analysis of these TLS tensors shows that the librations are of low magnitude and their eigenvectors  $L_i$  nearly parallel to the molecular inertial axis  $(L_i)$  quasi-parallel to the dipolar axis) (table 3).

At 138 K the  $L_1$  and  $L_2$  terms perpendicular to the dipolar axis decrease significantly, when  $L_1$  does not and takes into account the uniaxial rotation effect. The *T* translational tensor is quasi-isotropic. The deviations, between the anisotropic temperature factors refined by an independent-atom model and those calculated from the TLS tensors, are greater for the C—C $\equiv$ N atoms group but not significantly. One cannot conclude on a possible deformation of the C—C $\equiv$ N atoms, proup, perhaps because of the spherical atomic scattering approximation.

A glassy crystal: I-cyanoadamantane

# 3.5. Lattice relations between the monoclinic and cubic phases

Taking the centre of mass of a molecule as the origin, the vectors defining the centres of mass of the first neighbouring molecules describe a pseudo-rhombohedral lattice corresponding to a pseudo-face-centred cubic lattice. One obtains the following relations between the monoclinic (M) and pseudo-cubic (C) base vectors:

$$A_{C} = I(C_{M} - A_{M}) \qquad A_{M} = -A_{C} + I(B_{C} - C_{C})$$

$$B_{C} = B_{M} + I(A_{M} + C_{M}) \qquad B_{M} = I(B_{C} + C_{C})$$

$$C_{C} = B_{M} - I(A_{M} + C_{M}) \qquad C_{M} = A_{C} + I(B_{C} - C_{C}).$$

$$I$$

Figure 8. The pseudo-cubic parameters  $A_c$ ,  $B_c$  and their ratio plotted against temperature.

The angles between the  $A_C$ ,  $B_C$  and  $C_C$  vectors do not vary significantly with temperature and their values are always in the range 87° to 94°. The variations with temperature of the pseudo-cubic parameters  $A_C$  and  $B_C = C_C$  calculated from the corresponding ones of the monoclinic phase as well as the  $A_C/B_C$  ratio are reported in figure 8. This ratio increases and tends to 1.0 with temperature, which shows the evolution to the cubic phase 1 at  $T > T_i$ . The most puzzling result is that the dipolar axes are nearly parallel to the pseudo-cubic (111) and (111) directions.

3.6. Discussions and conclusions

A single crystal was grown at 253 K and its structure well resolved at T = 138 K and 240 K. Some particular results will now be analysed in detail.

4224 M Foulon et al

(i) At first, it was possible to confirm the threefold uniaxial rotation of the molecule in phase II. Its detailed mechanism is not yet known. (ii) At a given temperature lower than  $T_i$ , the difference between the unit cell volume of the cubic phases and that of phase II is low  $(\Delta V/V = 5 \times 10^{-1})$  (figure 10). This suggests that the molecular centre of mass arrangement is not very much altered. From their positions, a pseudo-cubic lattice was built which tends to the cubic plastic lattice near  $T_i$ .

(iii) At the temperature  $T_i$ , this low variation of the volume, compared with other compounds (CI-ADM or adamantane  $\Delta V/V = (6-8) \times 10^{-1}$ ), is certainly related to the quasi-static dipolar disorder (100 kHz) in phase 1.

Nevertheless, at  $T_i$  the dipolar axes must rotate from a direction (111) or (111) of the pseudo-cubic lattice ( $T < T_i$ ) to the six directions (001) of the cubic one ( $T > T_i$ ). This reorientation involves rotations of about 50° along the twofold axes of the pseudo-cubic lattice (parallel to  $B_{M_i}, B_M + C_M, B_M - A_M$ ), which implies an impurtant steric hindrance. This leads to the breaking of the crystal. In spite of this difference concerning the dipolar axis directions, the antiferroelectric order found in the monoclinic phase subsists locally in the cubic plastic phases (as deduced from the Kirkwood g correlation factor (Amoureux *et al* 1983)). The recent neutron and x-ray diffusion experiments (Descamps *et al* 1983) suggest that this local order may be retained in the glassy phase.

In the pseudo-cubic lattice description of phase II, the parameter  $A_c$  is always lower than  $B_c = C_c$ . Accordingly, a relation between the real monoclinic lattice and a pseudo-quadratic one can be considered. The comparison of the low-temperature ordered phase of CN-ADM with that of adamantance is of interest. In adamantance (Donohue and Goodman 1967), the lattice is quadratic and the threefold molecular axes have nearly the same orientations as in CN-ADM. Furthermore, the ratio  $A_c/B_c$ 

Figure 9. Projection on the AOY plane of the three metimus carbons not bounded to the  $-C \equiv N$  group fixed along the (001) axis.

(deduced from the quadratic parameters) is 0.953 for adamantane at 4 K below  $T_1$ , which is comparable with that of CN-ADM under the same conditions: 0.93.

4. Structures of the cubic phases and relationship with the molecular motions

The plastic phase has a FmJm structure (Amoureux and Bée 1979) with four molecules in the cubic cell (lattice parameter a = 9.81 Å at 293 K). The molecular dipolar C—C=N axis can randomly take six orientations, the molecule along the (001) directions. For each of the six dipolar orientations, the molecule can occupy four distinct equilibrium positions deduced from each other by 30° rotations around its threefold symmetry axis (figure 9). In the glassy phase, x-ray diffraction data on several single crystals have been collected at 113 K with and without annealing. The detailed analysis of these structures is now being processed, but is not straightforward and must be improved. Moreover the evolution at the glassy transition of the Bragg peak intensities has not been investigated so far. However the first analyses of the experimental data have shown that the molecular equilibrium positions are the same as in the plastic phase. The volume of the cubic lattice (Foulon *et al* 1983) in the disordered phases (1, 1', 1₀) is very close (figure 10) to that of the monoclinic cell in the ordered phase, which is very different from other glassy transition.

According to this structural description, two very different reorientations may exist in the cubic phases (figure 11): (i) Uniaxial rotations which are certainly fast as a result of a weak steric hindrance. These uniaxial rotations may be of order 3 or 12 around the molecular  $C-C \equiv N$  axis with corresponding residence times  $r_{a12}$ .

Figure 11. An example of packing in the (001) plane.

(ii) A tumbling reorientation of the dipole moment between the (001) axes. This tumbling motion, related to a large moment of inertia, is certainly very slow as it corresponds to steric hindrance between first and secind neighbouring molecules and then involves a huge local distortion of the cubic lattice. The jumps of the dipolar C-C=N axis between next neighbouring equilibrium positions are the most probable and they correspond to reorientations with respect to the (111) cubic lattice axes characterised by a residence time  $r_{ci}$ .

The microscopic description of the glassy state requires a knowledge of the temperature evolution of all these residence times. The best technique to provide such different residence times is certainly nuclear magnetic resonance (NMR).

5. Spin-lattice relaxation time  $T_{12}$  in ¹H NNR

The longitudinal relaxation time  $T_{12}$  has been measured from 113 K to 454 K in ¹H NMR at  $f_0 = 200$  MfHz. We have not obtained experimental results in the metastable phase [1'] between 172 K and 238 K as a result of the recrystallisation of cyanoadamantane. It is well known in NMR that the minimum values of  $T_{12}$  are observed when the residence times recorresponding to the molecular motions are about  $r \approx (2.xf_0)^{-1} = 8 \times 10^{-10}$  s. In cyanoadamantane the first at high temperatures corresponds to the slow dipolar tumbling ( $r_{c1}$ ) and the first at high temperatures to the uniaxial rotations ( $r_{m12}$ ). One can see from figure 12): that below 330 K only the uniaxial rotation is observed.

The analysis of the experimental results shows that the values of  $r_{CI}$  deduced from  $T_{1Z}$  between 330 K and 454 K are exactly the same as those deduced from dielectric relaxation (Amoureux *et al* 1983, 1984). These last studies had also shown that the dipolar reorientations are completely frozen at  $T_{x}$  with a Vogel-Fulcher law. The glassy state of cyanoadamantane is characterised by a static disorder for the dipole moments. An incoherent quasielastic neutron scattering (10NS) experiment (Bét *et al* 1980) has demonstrated that in the plastic phases the uniaxial rotations are of order 12. The values of  $T_{m12}$  deduced from the  $T_{1Z}$  measurements between 238 K and 35.) K are identical to those obtained from 10Ns.

(s) n

Figure 12. Longitudinal relaxation time  $T_{12}$  at  $\beta_a = 200$  MHz versus 10/T. The triangles corresponding to the monoclinic phase were obtained at  $\beta_a = 30$  MHz. The values of  $T_{12}$  calculated with a single residence time following an Arthenius law and corresponding to the experimental points between 150 and 330 K and in the glassy state below 150 K are represented by the broken curve.

In the glassy state, the value of  $T_{12}$  at  $T_{3}$  is in good agreement with the experimental spin-lattice relaxation times observed between 238 K and 330 K. Moreover the experimental and calculated minimum  $T_{12}$  values at 150 K are in very good agreement (155 ms). However when the temperature is lower than 150 K the experimental values of  $T_{12}$  are always much smaller than the corresponding ones calculated with a single residence time  $T_{m12}$  following an Arrhenius law between 113 K and 350 K.

Two hypotheses can be put forward to explain this difference:

(i) The uniaxial rotation, which is of order 12 above  $T_d$ , would become of order 3 below  $T_d$ . However it seems difficult to believe that the activation energy corresponding to this rotation of 120° observed at low temperatures (2.2 kJ mol⁻¹), can be smaller than that corresponding to the rotations of 30° observed at high temperatures (10.5 kJ mol⁻¹).

(ii) In the glassy state, the uniaxial rotations would correspond to a distribution of residence times as observed in the  $\beta$  relaxation' in usual glasses.

With these experimental data we cannot specify more accurately the molecular motions in the glassy state. Therefore we intend to carry out similar studies of  $T_{12}$  and  $T_{12}$  in this glassy state with a very low experimental frequency  $f_0$  of 10 or 20 MHz. At the same time we shall measure the lows diffusion in the same temperature scale between 100 K and 170 K. Taking these experiments all together we hope to obtain a very detailed picture of the molecular motions in the glassy state. In the ordered monoclinic phase there exists only one equilibrium position for the molecules which can then only carry out threefold uniaxial rotations between indistinguishable positions. The corresponding

Résumé. — Le cyanoadamantane cristallise dans une phase cubique plastique à l'empérature ambiante et présente une phase vitreuse en dessous de 170 K en cas de trempe rapide. Pour ces deux phases, la maille est cubique à faces centrées avec un groupe d'espace moyen Fm3m (Z = 4). Les structures à 295 K et 110 K ont été résolues dans l'hypothèse des molè-ules rigides. Deux méthodes ont été utilisées pour décrite le désordre : le modète de Frenkel et une densité électronique de symétrie cylindrique. Les facteurs de Debye Waller ont été pris en compte par les tenseurs T.L.S. Pour les deux phases, les deux modètes montrent que l'axe dipolaire de la molécule prend l'une des six orientations équivalentes (001) du cube. La densité électronique du groupe adamantyl autour de cet axe est quasiment constante. Lorsque les molécules présentent un arrangement (anti) ferroélectrique. l'encombrement stérique entre les groupes adamantyl est plus important dans la phase vitreuse; il exclut, par rapport à la phase plastique, quelques orientations relatives des molécules autour de leur axe dipolaire. Le paramètre de la maille cubique ainsi que l'intensité de deux réflexions de Bragg ont êté mesurés en fonction de la température. Il y a un changement significatif dans la pente de la courbe du paramètre de maille près de la température de transition de la phase vitreuse.

Abstract. — The cyanoad: mantane molecule crystallizes in a plastic cubic phase at room temperature and displays a crystalline * glassy phase * by rapid cooling below the glassy phase transition temperature  $T_p = 170$  K. In both cases the cell is f.c. with average space group Fm3m(Z = 4). Their structures are solved at 295 and 110 K in the framework of rigid body molecules. Two descriptions are used to describe the disorder : a Frenkel model and a cylindrical electronic density. The Debye Waller factors are described by the classical T.L.S. tensors. For the two phases, the two models show that the molecular dipolar axis can randomly take six orientations along the [001] directions and that the average electronic density for the adamantyl group around this axis is quasi-constant. When two first neighbouring molecules have (anti-) parallel orientations, the steric hindrance between the adamantyl groups is more important in the glassy phase and prevents some relative orientations around the dipolar axis. The lattice parameter and the intensities of two selected Bragg reflections have been measured versus temperature. The slope of the lattice parameter curve exhibits a significant change near the glassy phase transition.

## 1. Introduction

ANNEXE A-XI-3

The existence of glassy phases obtained from the quenching of molecular crystals in their plastic phase has been demonstrated by Adachi *et al.* [1]. In the glassy phase, the average translational order of the plastic phase is preserved, but the orientational disorder would be frozen. Cyclohexanol is a well-known case in which the glassy phase can be easily obtained and is, for the moment, the only example of a glassy crystal b intensively studied 11-41.

In a preliminary paper [5], differential scanning calorimetry, X-ray and Raman experiments show the existence of a glassy phase in cyanoadamantane when the sample is quenched rapidly. The phase transition sequence, when reheating, is summarized in figure 1 in case of fast quenching, slow cooling and slow heating [6].

In its plastic phase, cyanoadamantane crystallizes in the cubic system with space group Fm3m. The  $-C \equiv N$  dipolar axis can randomly take six orientations along the four-fold axes of the cube [7]. The relaxation time for this tumbling motion, measured by dielectric relaxation at room temperature, which is  $r_e = 3 \times 10^{-7}$  s shows that this motion is slow [8]. On the other hand, uniaxial rotation of the molecule around its dipolar axis at room temperature occurs at higher frequencies :  $r_{un} \simeq 10^{-14}$  s [9]. When the sample is slowly cooled, there is only a plastic to ordered phase transition at  $T_c = 280$  K. In this

Fig. 1. --- Phase transition sequence of 1-cyanoadamantane.

ordered phase, which is monoclinic with space group C2/m, the dipolar axes of the molecules exhibit an antiferroclectric arrangement [6]

comparison of the structures of the plastic phase and of two selected reflections versus temperature are given section 3. In section 4, the groundwork for the Frenkel model and the cylindrical electronic density mantane. Results and discussion of these two methods for the structure resolution are given in section 5. A The purpose of this paper is the determination of the structure of the glassy phase of cyanoadamantane by X ray diffraction. Then in section 2, the experimental arrangeneent is briefly explained. Comments on the variation of the lattice parameter and the intensities description are developed in the case of cyanoadathe glassy state is drawn. g

## Experimental conditions

range order. Then, the crystal was reheated by steps Thus, the quenching of the single crystal of cyanoadamantane was obtained, from the plastic phase at room temperature, by a cooling rate of about 7 K per minute down to 160 K. For one experiment, the temperature was lowered immediately to 110 K; for another, the crystal was annealed for 16 hours at 160 K before the temperature decrease. In both cases, the data collection of the intensities of Bragg reflectious was performed at 110 K. No significant differences are observed on the diffracted intensities showing no inducate of the anacating at 160 K on the long gen flow. With this apparatus, it is easy to get an Measurements were performed on an automatic X-ray diffractometer (PW 1100) with the MoK, radiation mated with a pyrolytic graphite crystal. The low temperature was obtained with a cold gaseous nitroimportant fall of the temperature in a few seconds. (1 = 0.7101 Å). The incident beam was monochro-

in order to measure the lattice constant and intensities Further on, we shall discuss only the structure of the of selected Bragg reflections at different temperatures. annealed glassy phase.

To collect intensities, U-2 U scans were used, with an unvarying scan width of 1.4" and a scan speed of 0.42° per minute in 0. The maximum value of 0 was

 $31.5\left(\frac{\sin\theta}{\lambda} < 0.74\right)$  311 reflections in an octant of the

non equivatent reflections. The crystal size was  $0.3 \times 0.3 \times 0.3 \text{ num}^3$ . Data were corrected for Lorentz reciprocal lattice were measured corresponding to 106 and polarization effects, but no absorption correction was applied.

The lattice parameters and the observed Brugg intensities lead to a f.c.c. tattice with 4 molecules per F23 and Fm3 are rejected according to the systematic condition  $|F(hkt)| = |F(\vec{k}, h, t)|$  verified on all the unit cell. Among the five possible cubic space groups, independent measured reflections

## 3. The glassy phase of cyanoadamantane.

tions have the sume experimental width as in the plastic phase (F.W.H.M.  $\approx 0.18^{\circ}$ ) and no small peaks appear in the vicinity of the Bragg peaks : the sample After the quenching of the crystal, the Bragg reflecin the glassy phase is still a single crystal.

decreases slightly during the first half-hour, but the determination of this variation is inaccurate ( $\Delta a \leq$ sured from 20 scleeted Bragg reflections. At the beginning of the annealing, the fattice parameter During the annealing, the lattice constant is mea-0.01 Å). ŀ

crystal; while  $\alpha_s = 1.64 \times 10^{-4}$  K⁻¹ for administrate [11] and 1.85×10⁻⁴ K⁻¹ for succinonitrile [12] in their plustic phase.  $\alpha_x$  values for cyanoudamantane seem to be intermediate between ordered and orientationally disordered molecular crystals. The extra-From the lowest temperature obtained during this cyanoadumantane are to be noted. By comparison for hexamethylenetetramine [10], which is an ordered In the temperature range of the glassy phase, there appears a small change in the slope of the lattice cons-10- * K - 1. Sumilar values for linear thermal expansion coefficient in the glassy state and in the plastic phase of with other molecular crystals,  $\alpha_x = 0.65 \times 10^{-4} \text{ K}^{-1}$ experiment (110 K) up to  $T_{\mu}$ , the lattice parameter is measured and its value is plotted versus temporature on figure 2. The T, temperature is determined by the crystal breakage. This damage occurs in the metastable phase and is casily observed on the width and intensily of the Bragg reflections. To compare with the plastic phase, the fattice parameter is also measured from 235 K (in the supercooled plastic phase) to 300 K. tant at 150 K : for lower temperatures the linear thermal expansion coefficient is  $\alpha_{s} = 0.82 \times 10^{-4}$  K ⁻¹ and between 150 K and T, its value is  $\alpha_s = 1.08 \times$ 10-* K-1 In the plastic phase a, equals 1.10 ×

cell versus temperature.

polation of the lattice parameter at  $T_a$  from the  $x_a$  value of the plastic phase leads to a = 0.690 Å, which is shows no discontinuity over the scanned range of close to the experimental value 9.689 Å (Fig. 2). This stores that the variation of the lattice parameter cmpcrature.

The intensities of two selected Bragg reflections have been measured versus temperature in the glussy phase (Fig. 3) Experimental conditions are exactly the same as for the data collection. For the two reflections (3, 1, 1) and (4, 0, 0), there is a normal temperature dependence of the intensity up to 160 K (10 K below T_a), the small decrease of the intensity corresponds to the normal increase of the Debye Waller factor with temperature. Between 160 K and 70 K, there is an important decrease of the intensity 13 % for (3, 1, 1) and 17 % for (4, 0, 0).

## 4. The fitting procedure.

low temperature monoclinic phase (Table I), [6]. The the disordered structure of cyanoadamantane has molecular distances and from the angles found in the irce molecule has C3, symmetry. In its plastic phase, The atomic coordinates are deduced from the intraheen solved using three different models : (i) by means of a Frenkel model. In this case, the molecule of cyanoadamantane is assumed to he in one of its equilibrium positions. Bust fits have been obtained when the C-N group is along one of the six fourfold axes of the cubic cell. The disorder along the axial -C-N group is taken into account by

structure factor relation. For cyanoadamantane, the - to the dipolar axis [18]. The R and R_w factors present minimum value of n is 12 and the O range of the X-ray measurements is not pertinent to give significant

our investigation has been limited to the constant cylindrical description

5. Structure resolutions - results and discussion.

5.1 DIFFICULTIES IN THE REFINEMENT. - Some difficulties limit the possibilities in this structure reli-Dement :

values of  $J_{1,2}(Q_{11}, \rho_1)$  for carbon shells. For this reason,

(i) The small number of significant independent structure factors limits the set of varying parameters. The scale factor and the T and L tensors are strongly correlated

(ii) The high ratio of diffracted intensities leads to a critical study of the weighting scheme.

(iii) The high molecular orientational disorder appears to be taken into account by the Debye Waller factors, and leads to abnormal values of the librational thermal parameters.

5.2 RESULTS WITH THE FRENKEL MODEL. - To take into account the axial disorder with the Frenkel model, we have analysed models with 2.4 or 8 couilibrium positions around the C=N axis using T.L.S. tensors with a C_{3v} symmetry.

5.2.1 Two positions. - The description with two positions corresponds to the F43m space group and is dismissed because of the poor quality of the refinements (R = 13.2 % and  $R_{w} = 19.7$  % for the glassy phase) and the negative value of the L11 parameter.

5.2.2 Four positions. - The refinements of the structures, with four uniaxial equilibrium positions, give the same results for the two possible distinct orientations (a molecular plane coincides with the [100] or [110] planes), and this proves their coexistence in the crystal. This leads to a Frenkel model with eight equilibrium positions.

5.2.3 Eight positions. - The results obtained with eight uniaxial orientations confirm the previous one and give no significant decrease of the R and  $R_{w}$ factors. Furthermore, this disorder description leads to an electronic density distribution quite similar to a cylindrical one.

5.2.4 Discussion of the Frenkel model. - This discussion concerns only the case with four positions and a T.L.S. adapted to a C., symmetry. The difficulties to refine the structure with a Frenkel model come from the fact that the  $L_{11}$  coefficient has no physical meaning.

This parameter is very sensitive to the disorder around the dipolar axis and does not really measure the librational amplitude of the molecule. To take into account this rotational effect on the bond lengths we introduce a shortening of the atomic distances

a minimum for too high a relative shortening  $(3 \times 10^{-3})$ and for  $\sqrt{L_{11}} = 14.4^\circ$ . With the twelve equivalent positions for a carbon atom of the adamantyl group and for a given direction of the -- C=N group, the rotational probability function for such an atom can be calculated using a Gaussian distribution :

$$P(\phi) = \frac{3}{12(2 \pi L_{33})^{1/2}} \sum_{i=1}^{12} \exp\{-(\phi - \phi_0^i)^2/2 L_{33}\}$$
(3)

in which  $\phi_{\alpha}^{i}$  is the *i*th equilibrium angle value. The factor 3 is the number of the atoms on the shell, This rotational probability function drawn on figure 4 nearly accounts for a cylindrical description. Using relation (2) for the  $P(\phi)$  probability function limited up to s = 1, one gets a very small value for the first term.  $a_{12} = 0.0034$  for  $\sqrt{L_{33}} = 14.4^\circ$ . This fact explains the equivalent success of the model with 4 and 8 uniaxial equilibrium positions and the favourable result of the refinements with the cylindrical model as will be discussed later.

5.2.5 Four positions with T.L.S. adapted to a symmetry. -- Last attempts were made with T.L.S. tensors taking into account the a symmetry with four equilibrium positions. 14 parameters are to be refined and the improvement of the results is not significant. This model has not been retained either

5.3 RESULTS WITH THE CYLINDRICAL MODEL. - For both phases, the cylindrical description and the Frenkel model with four positions lead to about the

Fig. 4. --- Rotational probability function around the dipolar axis for a carbon atom of the adamantyl shell. Full line : calculated from relation (3) with the Frenkel model. Mixed line ; uniaxial free rotation model  $f(\phi) = 3/2 \pi$ .

42

As in the first method, the orientational probability displays a maximum when the  $-C \cong N$  group is along the fourfold axes of the cube [13]. (iii) by a model intermediate between the previous ones, where the molecule can take many orientations

around the dipolar axis. This can be described through a cylindrical electronic density for the atoms of the adamantyl group. As for model (i), dipolar axes occupy randomly the six fourfold axes of the cubic cell [7]

If we take into account the relaxation times of the two reorientational motions of the molecule (tumbling and uniaxial rotation), and the good location of the C=N groups in the cell, the first and third methods vield the best fits. In the following, the structure of cyanoadamantane in its glassy phase will be solved with a Frenkel and a cylindrical description.

In both cases, the whole molecule is regarded as a rigid body and the ORION program [14] is used for the Frenket model. For the cylindrical description, refinements are performed with an ORION version, modified by the authors.

The weighting scheme  $W(F) = \frac{1}{\sigma(F)}$  used in the fitting procedure is taken as  $\sigma(F) = K\sigma_0(F)$ , with  $\sigma_0(F) = \sqrt{\sigma_0^2 + E^2 F^2}$ . The factor K is the multiplicity of the independent Bragg reflections. It is introduced in the least squares procedure to restore the very different multiplicity of the reflections in the cubic system.  $\sigma_c$  is the usual counting standard deviation, while the factor E is an adapted coefficient which reduces the high contribution of some very strong reflections (200, 111, 311, 400) compared with the others. The same structure fitting procedures were performed for the plastic phase and the glassy state in order to make a comparison. A reflection is considered as observed when  $F \ge 3 \sigma_0(F)$ , there are 42 independent such reflections for the plastic phase and 84 for the glassy state.

4.1 THE FRENKEL MODEL. - As for the plastic phase, the prototypic molecule of symmetry C_{1n} is chosen with its C-C=N group lying along the [0, 0, 1] cubic direction. For symmetry reasons the dipolar axis can then take six orientations. The dielectric relaxation measurements [15] show that this disorder is static in the glassy state. Taking into account the fourfold cubic axis, the axial disorder around the C--C=N group can be described by 2.4 or 8 discrete equilibrium positions. The three space groups which remain possible, are F432, F43m and Fm3m. In order to simplify the refinement procedure, we assume that a molecular mirror coincides with a [100] or [110] lattice plane. In this case the Fm3m and F432 space groups lead to the same equilibrium positions. For F43m, there are only 2 equivalent positions around the dipolar axis when a molecular symmetry plane coincides with a [1, 1, 0] plane. The Fm3m space group introduces 4 or 8 (distinct) equilibrium positions,

the fourfold axes of the cubic cell and  $p_1 = 1/6$ .  $Q_{\mu_1}$ and Q₁, are, respectively, the parallel and perpendicular parts of the scattering vector for the ith orientation of the rotation axis. f(Q) is the scattering factor of atoms of the *i*th shell and J_n is the zeroorder cylindrical itessel function.  $W_{\mu}(Q)$  is the Debye

Finally, the mass centre of the molecule, located by

symmetry arguments at (0, 0, Z_1) is able to shift

Assuming a rigid group for the molecule, the thermal

vibrations may be described by the T.L.S. tensors [16].

The symmetry of one molecule and its neighbourhood

tensors. According to the local order we shall consider

only the  $C_{\lambda_n}$  and  $\sigma_n$  cases. For the former, the local

order is assumed to be uniaxial of order n (n multiple

of 3) around the -C=N axis, while for the latter,

it displays a mirror coinciding with one of the mole-

cules. When we add the scale factor and the value Z.,

of the mass centre, there are 7 independent parameters

4.2 CYLINDRICAL ELECTRONIC DENSITY DESCRIPTION .---

The r, vector joining the /th atom to the molecular mass

centre is expressed in a cylindrical system  $\mathbf{r}_i = (p_i, \psi_i, z_i)$ 

in which the dipolar axis is along Oz. Atoms with

the same  $p_i$  and  $z_i$  set up a shell, containing  $n_i$  atoms.

Because of the uniaxial symmetry required for this

model, the coordinates of the mass centre are  $(0, 0, Z_{\rm m})$ .

Thus, for a continuous cylindrical electronic density,

The i sum runs over the shells of the molecule and

the i sum over all the possible orientations of the

rotation axis. p, is the probability of finding the

molecule with its rotation axis along the orientation i.

For cyanoadamantane, the rotation axes are along

 $x \exp \{ i Q_{\mu} (Z_{\mu} + z_{\mu}) \} J_{\mu} (Q_{\mu}, \mu_{\mu})$  (1)

in the  $C_{1_0}$  description and 14 in the  $\sigma_1$  one.

the structure factor is given by :

 $F(Q) = F(h, k, l) = \sum_{i=1}^{l} p_i n_j f_j(Q) e^{-W_{j,i}(Q)} \times$ 

along the fourfold axis of the cube.

Waller factor. It takes into account translational thermal vibrations of the whole molecule, as well as rotational ones around directions perpendicular to the rotation axis. The Debye Waller factor W (Q) is, in fact, expressed from the parameters  $T_{11}$ ,  $T_{33}$ and Lin introduced in the Frenkel model.

When the electronic density distribution is not constant, the probability to find an atom of the jth shell with the polar angle & becomes [17] :

$$P'(\phi) = \frac{n_1}{2\pi} \left\{ 1 + \sum_{i=1}^{\infty} u_{i*}^i \cos sn(\phi - \phi_0^i) \right\}$$
(2)

in which  $\phi_k^{\dagger}$  corresponds to an equilibrium position for the shell, n is the number of such equilibrium positions and  $\omega_{1}^{i}$  are coefficients; the factor  $1/2 \pi$ ensures normalization. In this case, cylindrical Bessel functions of order si are to be introduced in the

## (Received 10 October 1983; accepted 16 December 1983)

Dielectric properties of 1-cyanoadamantane  $C_{10}H_{12}CN$  are analysed with very low frequencies between 80 K and 320 K. The critical frequency in the (stable and supercooled) plastic phases does not follow an Arrhenius law. This behaviour corresponds to the glassy state of cyanoadamantane. However,  $\beta$  relaxation in the glassy phase certainly does not exist in this compound.

## 1. INTRODUCTION

For some years we have undertaken an extensive and comparative study of substituted adamantanes. This series of compounds are particularly interesting owing to their high symmetry and to the fact that most of them are in a cubic plastic phase at room temperature. One of the most interesting substituted adamantanes is 1-cyanoadamantane (CN-ADM): C₁₀H₁₅CN. Its interest arises from its long cylindrical substituent, from its very large permanent dipole moment ( $\mu_v = 3.83$  D) and from its being in a plastic phase at room temperature (melting point  $T_m = 458$  K). This compound, formally known as 1-cyano tricyclo [3, 3, 1, 1] decane, is composed of globular molecules and is obtained from adamantane, C1011, by substituting a cyano group onto a methine carbon (figure 1). Microwave spectra [1] and ¹³C NMR chemical shifts [2] have shown that this substitution does not change the rest of the molecule whose symmetry is then  $C_{3\nu}$ . The molecular motions of this compound have been studied by Incoherent Quasi-elastic Neutron Scattering (IQNS [3]), 'II-NMR [4] and high-frequency dielectric relaxation [5]. In these three experiments we have never really observed the transition between the plastic and the brittle phases. In order to explain this lack of transition we have then carried out some DSC experiments.

## 2. CYANOADAMANTANE IS A GLASSY CRYSTAL

The possible existence of a glassy crystal phase obtained by quenching of some molecular plastic crystals has been discussed [6]. If the crystal in the

plastic phase (phase I) is cooled rapidly enough to prevent the transition towards the low temperature ordered phase (phase II), the disordered system is supercooled and ultimately goes into a glassy state (phase  $I_g$ ). That is the case for cyanoadamantane. The successive peaks in the DSC curve (figure 2), obtained after quenching from 300 K to 90 K, can be interpreted as follows (figure 3):

- (i) The endothermic anomaly at  $T_{\mu} = 170$  K is due to a glass transition from the glassy crystalline phase  $I_{\mu}$  to a metastable phase I', which we shall see is the supercooled plastic phase.
- (ii) The exothermic irreversible transition at about 205 K corresponds to the transition from the metastable form (I') to the low temperature brittle phase (II). As usually observed in many plastic crystals there can exist a noticeable delay in the transformation from the disordered state to the ordered one ( $1' \rightarrow II$ ). This delay is more or less important according to the crystals and therefore this transition runs over 50 K in this powdered sample.
- (iii) The endothermic peak at about  $T_{\rm t} = 280$  K is the usual non plasticplastic transition. As in all the other known glassy crystals [7] the ratio  $T_{\rm w}/T_{\rm t} = 0.6$  lies between 0.5 and 0.7.

When the temperature is lowered slowly from 300 K, the plastic phase is supercooled and the transition to the brittle phase occurs below 250 K at a temperature which depends on the cooling rate. X-ray diffraction data have been recorded on single crystals in both the brittle and glassy phases. The Dielectric properties of cyanoadamantane

brittle phase (11) is monoclinic (space group C2/m) and an anti parallel local order has been pointed out [8].

:

The glassy  $(I_{w})$  and the plastic  $(I, \Gamma)$  phases have exactly the same f.e.c. structure [9, 10] with four molecules in the cubic cell. The dipolar C-C $\equiv N$ axis can take randomly six orientations very closely located along the  $\langle 001 \rangle$ directions. The analysis of the Bragg peak intensities have shown that for each of the six dipolar orientations, the molecule can occupy four distinct equilibrium positions derived from each other by 30[°] rotations around its three-fold symmetry axis. In figure 4 we have shown an example of packing and one can see that for each particular molecule some positions are impossible consequent on the steric hindrance between first and even second mext-neighbour molecules : there thus exists a local order. However when a macroscopic sample is observed, all the equilibrium positions for the averaged molecule have the same probability.

According to this structural description, two very different motions may exist in the cubic phases : a fast quasi-free uniaxial rotation [3, 4] around the  $C-C \equiv N$  group and a slow tumbling reorientation of the dipole moment between the  $\langle 001 \rangle$  axes of the cubic lattice [5]. At room temperature, in the plastic phase, the corresponding frequencies are very different : 10¹⁴ Hz and 10⁵ Hz. Raman spectra recorded in the glassy phase [11] have shown the vanishing (with respect to the plastic phase) of the low frequency contributions, which suggests that a local order takes place in the glassy phase of CN-ADM. Dielectric relaxation experiments had then to be carried out at low temperatures to see if the slowing down of the dipolar reorientations is implicated in the transition to the glassy state.

Dielectric properties of cyanoudamentane

165

3. EXPERIMENTAL CONDITIONS FOR THE DIELECTRIC RELAXATION OF CN-ADM

The complex permittivity of CN-ADM has been obtained directly with a spectrometer using a data sampling process and a digital calculator at low frequencies [12] and with an automatic impedance bridge (IIP 4275 A) monitored by a microcomputer (IIP 85 F) at higher frequencies.

Generally, the experiments were carried out at fixed frequency, the experimentally varied parameter being the temperature. Eight high (above 10 kHz) and three low (under 100 mHz) frequencies were used. When the samples were quenched the temperature was decreased from 300 K to 80 K in about 600 s. The uncertainty in the position of each relaxation peak is about 0-25 K. The temperature gradient in the sample (0-5 K) was always identical with our experimental conditions and thus does not affect the relative temperature accuracy. After quenching, when the sample was warmed (heating rate 0-5 K/min), the complex permittivity was measured every 0-25 K in the relaxation case.

Since the material under investigation has cubic symmetry, the complex permittivity is isotropic and can be measured directly on a powder sample. Therefore, the experiments were performed on homogeneous mixtures of powdered CN-ADM (concentration  $\theta$ ) with air. In a recent paper [13] it was shown that the dynamical dielectric properties of a concentrated mixture are well described by Büttcher's formula:

Figure 5. Experimental complex permitricity (u = 0.55) corresponding to a slow (= 0.5 K/min) cooling from the plastic phase. The frequency is indicated in KHz.

Dielectric properties of cyanoudamantane 167	This hysteresis effect was pointed out more obviously in a third series of experiments in which the temperature was first increased from 120 K to 315 K and then decreased to 288 K. Indeed one can see in figure 6 that the complex permittivities are different depending on whether the temperature is increased from the plastic phase.	Two different fillings of the cell were successively used, but corrected to the pure bulk material they gave the same reaults. The samples were successively quenched quickly and warmed showly. For the three experimental low frequencies (13, 504, 82, 6 mHz) the complex dielectric permittivity showed the same aspect (figure 7) which can be interpreted as follows: (1) Between 90 K and 170 K, in the glassy phase (L ₂ ), the critical frequency for corresponding to the maximum value $\epsilon^{2}_{13}$ of the loss factor) is lower than 50 mHz: $\epsilon^{2} = 0$ . Another relaxation zone, below 90 K, and with these three experimental frequencies, is improbable as the $\epsilon^{2}$ value (27) corresponds to a quire possible cefractive index [1+]: $a = \sqrt{2.71}$ (15) $-16$ . Relaxation phenomena (fi any) in the glassy phase ( $\frac{1}{4}$ ) of the loss factor) is lower than 50 mHz: $\epsilon^{2} = 0$ . Another relaxation zone, below 90 K, and with these three reprimental frequencies, is improbable as the $\epsilon^{2}$ value ( $\frac{2}{3}$ ) of the loss factor) is lower than 50 mHz: $\epsilon^{2} = 0$ . Another relaxation zone, below 90 K, and with these three reprimental frequencies ( $\frac{1}{3}$ ) the glassy phase ( $\frac{1}{4}$ ) is $\epsilon^{2}$ ) of the loss factor) is below for the normal grander ( $\frac{1}{3}$ ) the solution of the interpretature ( $\frac{1}{3}$ ) the relaxation phenomena (called relaxation $z$ ( $\frac{1}{3}$ ) occurs in the metasus the function phenomena (called relaxation $z$ ( $\frac{1}{3}$ ) the solution $z^{2}$ ( $\frac{1}{3}$ ) the called relaxation $z^{2}$ ( $\frac{1}{3}$ ) the solution $z^{2}$ to $z^{2}$ to	
166 J. P. Amoureux et al.	where $\epsilon^*$ and $\epsilon_{exp}^*$ are respectively the complex permittivity of the single crystal and of the homogeneous mixture. The powder sample was put in a cylindrical capacitor 5 cm long with inner and outer conductor diameters respectively of 25·1 and 31·0 mm. For each different filling of the dielectric cell, a spectrum measured at room temperature allowed us to recalibrate, in a more precise way, these results ( $\theta \simeq 0.58$ ) with those obtained previously [5] with a larger concentration ( $\theta = 0.95$ ).	<b>1.</b> Itera requercies were used: 10, 20, 40, 100, 200, 400, 100, 2000 ktlz. In a first screep or event as the temperature was decreased abovy ( $-0.5$ K/min) from 331 K to 120 K. The corresponding complex permittivities (figure 5) agree with those previously published [5]. According to the temperature, the sample was in the stable 1 ( $7$ > 230 K) or in the supercoded I 'plastic plase. The transition from plastic to brittle phases was not obtained with these experiments, the temperature was them increased stores of septeriments the temperature was them increased stores of septements obtained in this case are identical to those of figure 5 only if the temperature is shifted by about 0 or 7 degree.	Figure 6. Experimental complex permittivity ( $\theta = 0.55$ ) corresponding to a slow warming

J. P. Amoureux et al.

Figure 8. Isofrequency Cole-Cole plot c versus c (82.6 mHz ; 9.5°C/min) with  $\beta = 0.57$ . The experimental points are corrected for single crystal. from  $\epsilon_x(l')$  to the static dielectric  $\epsilon_x(l')$ , and the loss factor  $\epsilon^*$  shows a relaxation aspect. The Kirkwood-Frohlich theory [15] (generalized to solids by Bordewijk [16]) allows the calculation of the static dielectric Kirkwood g factor which takes into account the short-range correlations between molecules :

$$g = \frac{1}{\mu^2} \left( \mu_1 \sum_{i} \mu_i \right).$$

If locally the dipole moments  $\mu$  are (anti) parallel, then g > 1 (g < 1). If there are no correlations or if the correlations arrange the permanent dipoles in a perpendicular way, then g = 1. If we assume that this theory is applicable in this metastable phase, one obtains an anti-parallel local order for this l' phase: g = 0.15 at 190 K. We have represented on figure 8 the Cole-Cole plot ( $\epsilon^*$  versus  $\epsilon'$ ) measured at 82.56 mHz. Obviously this curve corresponds to a Cole-Davidson macroscopic distribution

$$\epsilon^{\bullet}(\omega) = \epsilon_{\omega} + \frac{\epsilon_{s} - \epsilon_{\omega}}{(1 + i\omega\tau)}$$

If one assumes that the distribution does not change in the temperature range corresponding to the relaxation, the parameter  $\beta$  is equal to 0.57.

- (iii) At about 200 K, the CN-ADM changes from the metastable (1') to the brittle (11) phases. X-ray studies have shown [8] that in the monoclinic phase the dipole moments are ordered, which corresponds to the lack of relaxation phenomena:  $\epsilon^* = 0$  and  $\epsilon' = 2.7$ . This value of 2.7 for  $\epsilon'$ , identical in the glassy and brittle phases, is a new demonstration for the refractive index n = 1.6.
- (iv) At 280 K, CN-ADM transforms into the cubic plastic phase. The critical frequency  $F_c$  being equal to 120 kHz in this phase, the  $\epsilon'$  value is equal to  $\epsilon_s(1)$ . When the temperature increases from 280 K, cyano-adamantane presents some superficial conductivity visible at these low experimental frequencies (and and above 10 Hz : figure 5). Therefore  $\epsilon'$  and  $\epsilon'$  are not constant, but these variations do not correspond to the molecular reorientations.

Dielectric properties of cyanoadamantane

169

A very important question arises from the previous studies: is the metastable phase (1'), the continuation of the supercooled plastic phase? In order to elucidate this question, we carried out another experiment in which the temperature was decreased (-1 K/min) from 300 K to 120 K. At about 220 K a large proportion ( $\simeq 85$  per cent) of the sample transformed into the brittle phase, but the remainder relaxed at the same temperature as previously. This relaxation was visible only on  $\epsilon'$  (figure 9), because the experimental variations of  $\epsilon'$  were certainly too small ( $\epsilon'_{M}$  (calculated) = 0.07). The experimental critical frequency is identical when the temperature is increased from the glassy phase or lowered from the plastic phase. Therefore the three critical low frequencies have to be related to those already measured [5] in high frequency range.

Figure 9. Experimental complex permittivity (corrected for single crystal) corresponding to a slow cooling from the plastic phase with f = 50.4 mHz.

## 6. CONCLUSIONS

Obviously the critical frequency in the (stable and supercooled) plastic phases does not follow an Arrhenius law in all the temperature range above  $T_{\rm w}$  (figure 10). An Arrhenius law can only describe the critical frequencies above 100 Hz :  $F_{\rm o} = 2.03 \times 10^{11} \exp(-5940/T)$  Hz.

If one uses the phenomenological law of Vogel-Fulcher-Tamman :  $F_{\rm e} = F_{\rm e}^{\rm a} \exp(-T_{\rm e})/(T-T_{\rm e})$ , a good description of the critical frequencies between 0-03 and 10⁷ Hz is then obtained with:

 $F_{e}^{\alpha} = 60.2 \text{ GHz}, T_1 = 2176 \text{ K}, T_n = 107.1 \text{ K}.$ 

This description with respect to the temperature of the critical frequency is characteristic of compounds having a glassy state [7]. However, contrary

The glassy phase of 1-cyanoadamantane; a study of the molecular reorientations by high-resolution quasi-elastic neutron scattering

M Béett, M Foulont, JP Amoureuxt, C Cauchereuxt and C Poinsignont t Laboratoire de Dynamique des Cristaux Moléculaires (UA 801), Université des Sciences et des Techniques de Lille I, 59655 Villeneuve d'Aseq Cédex, France t Institut Laue-Langevin, 156 X, 38042 Grenoble Cédex, France

Received 25 March 1986

Abstract. Using the incoherent quasi-elastic neutron scattering (10NS) technique, the motions of 1-cyanoadamantane  $C_{in}H_{13}CN$  are investigated helow 170 K in the glassy phase obtained by rapid quenching of the room-temperature orientationally disordered phase. The broadening of the experimental spectra is evidence for the existence of rotations of the molecules about their symmetry axes on the timescale  $10^{-10}$ – $10^{-4}$  s. However, from a direct Fourier transform analysis, it is demonstrated that the experimental data cannot be described in terms of any simple jump model involving a single correlation time. In accordance with the conclusions of the studies by NNR and x-ray techniques, an interpretation based upon a distribution of the correlation times is proposed. Finally, we discuss whether this time distribution is a characteristic feature of this glassy state.

## **1. Introduction**

The existence of a new type of glasses was demonstrated by Adachi *et al* (1968): by rapidly cooling some molecular crystals, initially in their orientationally disordered phase (plastic phase), the normal transition into an ordered low-temperature phase can be avoided and the specimen passes into a 'glassy state'. A common description of such a phase is that the average translational order is preserved, but the orientational disorder is frozen. Because of the crystalline nature of these glassy phases, the study of them should provide a better understanding of the usual amorphous glasses.

This type of glassy transition has been observed for 1-cyanoadamantane  $C_{10}H_{15}CN$  (hereafter referred to as ADM-CN), shown schematically in figure 1. The molecule has the general shape of a globular adamantyl cage, onto which is bonded a rather elongated radical C = N. The resulting molecular symmetry is  $C_{3v}$ . The whole molecule bears a large dipole moment (3.9D).

The crystal structure of the FCC plastic phase (space group  $F_{mbu}$ , Z = 4) has already been described in some detail (Amoureux and Bée 1979, Amoureux *et al* 1981b), as also has the nature of the dynamical disorder. Several experimental techniques, i.e. NMR (Amoureux *et al* 1981a, 1986), dielectric relaxation (Amoureux *et al* 1983), and incoherent quasi-elastic neutron scattering (IONS) (Bée *et al* 1980) show that two types of molecular motions exist simultaneously. The first motion corresponds to the reorientation of the molecule's threefold axis (dipole axis) from one (001) lattice direction to

ANNEXE A-XI-5

338

Figure 1. A possible configuration of 1-cyanoadamantane molecules in the glassy state with an antiferroelectric arrangement (Foulon *et al.* 1985).

another, while the second is the rotation of the molecule about this axis. The former motion is strongly hindered by the first- and second-neighbouring molecules. Hence the mean residence time of the molecule dipolar axis along the (001) directions is rather large. Conversely, the latter motion appears to be more free. It has been described as 30° jumps among twelve equilibrium positions. The related correlation time  $r_{m_12}$  is about  $1.6 \times 10^{-12}$  s at T = 300 K. The ordered phase below T = 280 K is monoclinic, C2/m. The crystal structure can be described as a succession of parallel planes composed of molecules with their dipoles in antiparallel order, along one (111) pseudo-cubic direction (Foulon *et al* 1984). NMR measurements prove that the motion around the molecular threefold axis still exists, in spite of a strong steric hindrance (Foulon *et al* 1984). Amoureux *et al* 1986).

Below the glassy transition temperature ( $T_{\rm g} \simeq 170$  K), the glassy state exhibits the same average space group as the plastic phase, in which the molecules occupy the same equilibrium positions (Foulon *et al* 1985). X-ray and coherent neutron scattering measurements (Descamps *et al* 1985, Lefebvre *et al* 1985) have demonstrated the progressive increase in the numbers of interlocked antiferroelectric domains. The glass transition preserves the translational order and affects the molecular orientations.

Therefore, the knowledge of the evolution, as a function of temperature, of the dipole residence time among the equilibrium positions is an essential factor in obtaining an understanding of the exact mechanism of the glass transition.

Low-frequency dielectric relaxation measurements (Amoureux *et al* 1984, Pathmanathan and Johari 1985) have clearly shown that the dipole tumbling is frozen at  $T_g$ according to a Vogel-Fülcher law. Conversely, the uniaxial reorientation still continues to be observable using NMR below  $T_g$  (Foulon *et al* 1984, Amoureux *et al* 1986).

The tows technique permits observation of each individual scatterer inside a molecule

## 2. Experimental conditions

The experiments were carried out at the Institut Laue-Langevin, in Grenoble. The back-scattering spectrometer IN10 was chosen because of its high resolution in energy for the range expected to be relevant. Use of a powder sample enabled us to avoid a lot of technical difficulties linked with the growing and the cutting of single crystals with large enough area and small enough thickness to obtain a sufficient scattered intensity without significant contamination from multiple scattering. In theory, using a polycrystalline specimen rather than a single crystal leads to a loss of information because of the averaging over all the directions of the scattering vector Q. However, on the timescale of the experiment the dipolar orientational disorder can be considered static (Bée et al 1980). The scattering law related to uniaxial rotation has to be averaged over the six possible (100) directions, and the use of a single crystal would not actually provide much more information.

The following temperatures were chosen for the measurements: T = 138, 149 and 159 K ( $T_{\rm g} = 170$  K). Si [111] analysers were set up about the average scattering vector values, Q = 1.2, 1.55, 1.72 and 1.93 Å⁻¹, in order to avoid Debye circles corresponding to Bragg reflections ( $\lambda = 6.28$  Å). The instrument resolution was of the order of 1  $\mu$ eV (FWHM) for an energy range of the analysis of  $\pm 13 \,\mu$ eV. The multiple scattering did not need to be taken into account because of the very small thickness of the specimen, about 0.3 mm, corresponding to a transmission of 0.9 when the sample was perpendicular to the neutron beam. The flat sample,  $38 \times 35$  mm² in dimension, was oriented at  $45^{\circ}$  to the incoming neutrons. A rapid quenching was achieved by directly dipping the sample into liquid nitrogen and this was followed by a slow heating up to the required temperature. Thus, commencement of crystallisation into the monoclinic phase may be considered improbable.

Another series of measurements was performed at T = 159 K, where, for improving the instrument resolution, polished analyser plates were employed. The FWHM of the resolution function was decreased to about 0.42  $\mu$ eV. An even better value could have been obtained by using a polished monochromator, but we did not use one because we wanted to keep sufficient incident neutron flux. In this experiment, data were collected for only three values of Q, 1.31, 1.72 and 1.93 Å⁻¹.

The usual corrections for absorption, self-shielding and sample holder scattering were applied to the data, and then they were analysed on the basis of dynamical models.

## 3. Analysis of the experimental results

Basic hypotheses and fundamental expressions arising in 10NS have already been discussed at some length in reference textbooks (Leadbetter and Lechner 1979, Springer 1972) and will not be reported here. The relevant equation in the study of molecular

340 AI Bée et al

reorientations is the rotational scattering law

$$S_{\rm inc}(Q,\omega) = u_0(Q)\delta(\omega) + \sum_{i=1}^{n} a_i(Q) \frac{1}{\pi} \frac{v_i}{1+\omega^2 c_i^2}.$$

Ξ

which appears to be composed of two contributions. The first term on the RHs of (1) corresponds to a purely elastic scattering. The coefficient of the  $\delta$ -function,  $a_{0}(Q)$ , is called the elastic incoherent structure factor (EISF). It provides information about the geometry of the motion. The second term on the RHS is known to be quasi-elastic from the presence of the lorentzian functions. Their number, n, and their respective weights,  $a_{i}(Q)$ , depend on the precise model considered. Their half-widths at half-maximum  $r_{i}^{-1}$ , involve the different jump-rate probabilities per unit time for the molecule. The EIST and the quasi-elastic structure factors  $(a_{i}(Q))$  are linked together through the relation

$$u_0(Q) + \sum_{i=1}^{n} u_i(Q) = 1.$$
⁽²⁾

From the integration over the energy values of the spectra recorded at constant Q, it is clear from (1) that the EISF can be determined experimentally:

$${}^{n}(Q) = I_{d}(Q)/(I_{d}(Q) + I_{q}(Q))$$
(3)

where  $I_{
m cl}(Q)$  and  $I_{
m cl}(Q)$  are the elastic and quasi-elastic scattered intensities, respectively.

## 3.1. Analysis of the clustic scattering

Experimental values of the Ersi were obtained for ADM-CN in its glassy phase at each temperature by refining a purely phenomenological model to the spectra collected at each temperature by refining a purely phenomenological model to the spectra collected at each Q-value. Spectra predicted by this model were composed of a purely elastic contribution and of a quasi-elastic part, itself formed of two lorentzian functions, convoluted with the instrument resolution. The magnitudes of each of these three components and the widths of the lorentzian functions were introduced as parameters in the refinement procedure. Good fits were obtained (see figure 2). The quasi-elastic part of the spectra could be particularly well described by the combination of the two lorentzian functions. From the relative magnitudes of the elastic intensities, experimental values of the EISF were deduced and compared with those predicted by theoretical models.

The conclusions of the dielectric relaxation study are that the tumbling of the dipolar axis is frozen and the only relevant motions are the uniaxial rotations. This is the fundamental result from all our analysis. The molecule with symmetry  $C_{3\nu}$  is aligned along the (001) fourfold axes.

According to these symmetries, the time- and space-averaged structure, analysed by x-ray diffraction, indicates 12 equilibrium positions for one hydrogen atom (corresponding to four discernible molecular ones). This static description does not presume the dynamical one. In fact, in a jump-model framework, it can be assumed that one individual hydrogen atom can carry out uniaxial rotation over N = 3, 4, 6 or 12 sties.

The relevant correlation times,  $r_{\rm c}$  for these models are listed in table 1. They are easily evaluated from the general relation

$$r_{1}^{-1} = 2r_{11}^{-1} \sin^{2}(\pi i/N)$$

ions study of the glassy state of C₁₀H₁₅CN

The EISF  $a_0(Q)$  is an average over the *p* relevant incohercent scatterers within the molecule, rotating over individual circles of radii  $r_j$ . Expression (5) gives the EISF in the

case of a rotation of order three:

$$4_{u_{0}}(Q) = \frac{1}{3p} \sum_{j=1}^{n} \left(1 + 2 \frac{\sin(3^{j/2}Q_{L_{j}})}{3^{1/2}Q_{L_{j}}}\right).$$
(5)

The two models corresponding to N = 6 and N = 12 have EtsF values that are nearly the same, so the six-jump model will no longer be considered.

The structure factors, a(Q), for N = 12 are itlustrated in ligure 3. It also shows the comparison of the experimental EISF values with the theoretical values predicted by the models for N = 3, 4 or 12. Clearly, experimental values lie above the curve related to the twelve-site model, which was successfully used to interpret the 10NS data for the plastic phase, but appears completely inadequate for the glassy state. However, the most striking feature is the failue of the two other models (for N = 3 or 4) and especially that of the theore-site model, in spite of the larger amount of elastic scattering that it predicts.

The analysis of the elastic scattering part in terms of a uniaxial rotation associated with a unique residence time shows that this simple model disagrees with the experimental EISF. Table 1. Characteristic times for reorientational jump models for jumps between three, four and twelve sites.

Figure 3. A comparison of the experimental Erse values with the theoretical variations predicted by jump models among 3, 4 or 12 equilibrium sites. Typical error bars are shown. The quasi-classic structure factors for the twelve-site model have also been reported. The widths of the corresponding lorentzian functions are listed in table 1:  $(A) 1/r_1 = 0.134/r_1 (B) 1/r_2 = 0.5/r_1 (C) 1/r_3 = 1/s_1 (C) 1/r_4 = 1/s_1 (C) 1/r_4$ 

## 3.2. Analysis of the quasi-elastic scattering

It is possible to go one step further in the analysis of the quasi-elastic part of the spectra. Using a fast-Fourier-transform procedure, the direct deconvolution of the scattering functions  $S(Q, \omega)$  from the instrument resolution was performed, yielding the well known intermediate-scattering function

$$((Q,t) = \frac{t}{2\pi} \int S(Q,\omega) \exp(i\omega t) d\omega.$$
 (6)

It is worth pointing out that the three-site jump model involves a single correlation time and therefore a single lorentzian function in the quasi-elastic part of the energy spectra at any Q-value. The explicit expression for the intermediate-scattering function is

$$I(Q, t) = a_0(Q) + (1 - a_0(Q)) \exp(-t/\tau_{m_1}).$$
(7)

The function

$$\log(I(Q, t) - I(Q, \infty) = -t/\tau_{m_1} + \log(1 - u_0(Q))$$
(8)

should exhibit the same linear variation as a function of the time, *t*, for all *Q*-values. It is shown in figure 4 that at least two straight lines with distinct slopes can be observed, which proves that the molecular uniaxial motion cannot be described by a simple model with a single exponential term.

Now it must be pointed out that the intermediate-scattering functions corresponding to four and twelve sites involve n characteristic times (n = 2 or 6), but these times are linked together through relation (4) and depend on a single parameter,  $\tau_{n_1}$ , or  $\tau_{n_{12}}$ , the

Figure 4. A direct determination of the characteristic times from the experimental data ( T = 159 K. )

residence time between two jumps from one site to the neighbouring one. In figure 4 it is shown that the extremal values of the two slopes are in the ratio one to five. By referring to the expressions for the characteristic times listed in table 1 we can see clearly that the four-site model is not in accordance with this result, predicting a ratio of one to two. Such a difference is much larger than the error in the determination of the values of the two slopes in figure 4. We see by referring again to table 1 that the twelve-site model two slopes in figure 4. We see by referring again to table 1 that the twelve-site model could provide values of characteristic times with a ratio in the range obtained experimentally:  $r_2/r_1 = 0.268$ ,  $r_4/r_2 = 0.33$  etc; but the experimental values of the slopes do not vary as a function of Q, as shown in figure 4. Conversely, the relative weights of the lorentzian functions associated with the different characteristic times follow the Q-dependence of the structure factors (see figure 3). Therefore, the exponential terms related to short times should be predominant at large Q. That is not observed experimentally and it scems that the twelve-jump model must be discarded too.

## 3.3. Recrystallisation

A possible explanation of the anomaly in the clastic part of the scattering is the partial recrystallisation of ADM-CN from its glassy phase into its monoclinic low-temperature phase. As already mentioned, the method used for quenching the sample allows us to discard this hypothesis. The phenomenon of nucleation by irrudiation is improbable, as the experimental scattering spectra exhibit no variation with time. DSC experiments showed that the tendency towards recrystallisation is greater at temperatures near  $T_{i}^{c}$ . The first should then increase with temperature. In contrast, however, the experimental

Eist increases when the temperature is lowered. A partial recrystallisation of the product cannot explain why the value of the Eist is too high. Furthermore, it has no influence on the quasi-elastic part, because the 120° jumps between indistinguishable positions that are known to occur in the monoclinic phase (Foulon et al 1984) are far too slow to produce any appreciable broadening.

## **noiseussig.** 1.

01

The jump probability for a given molecule strongly depends on its local neighbourhood. In connection with the progressive increase in the numbers of antiferroelectric domains, shown to occur in the glassy phase from x-ray and coherent neutron scattering results, it is reasonable to assume that the immediate surroundings will not be the same for all molecules. Therefore, reorientations can be more or less favoured. A series of relaxation times is possible and the shape of the quasi-elastic spectra should be analysed under the assumption of a distribution of the relaxation times. This hypothesis is strengthened by the results of other experimental techniques. The study of the longitudinal relaxation times  $T_{\rm tr}$  in proton was clearly shows that the uniaxial motion still exists in the glassy phase.

The value of  $T_{12}$  at the glassy transition  $T_g$  coincides with the theoretical value predicted by simple extrapolation of the values in the plautic phase. This agreement shows that the glassy transition does not significantly change the frequency of the uniaxial shows that the glassy transition does not significantly change the frequency of the uniaxial to action. Below  $T_g$ , in the glassy state, the experimental values of  $T_{12}$  deduced from the values of  $T_{12}$  below  $T_g$ , in the glassy state, the experimental values of  $T_{12}$  deduced from the values of  $T_{12}$  below  $T_g$ , in the glassy state, the experimental values of  $T_{12}$  below  $T_g$  in the glassy state, the experimental values of  $T_{12}$  below  $T_g$  than above this temperature (9 kJ nuol⁻¹) below  $T_g$  than above this temperature (9 kJ nuol⁻¹). Decomes much smuch smallet (2.2 kJ mol⁻¹) below  $T_g$  than above this temperature (9 kJ nuol⁻¹). All these features of the glassy state can only be explained if a distribution of residence of  $A_{11}$  these features of the state of  $T_{12}$  below  $T_g$  than above this temperature (9 kJ nuol⁻¹).

times is assumed (Amoureux et al 1986). When the temperature is lowered, the thermal translational motions of the molecules are progressively frozen, as shown by the linear evolution of the average translation tensor (Foulon et al 1985). In the glassy phase of be interpreted as a static distribution of the centres of mass of the molecules about the mean sites of the cubic lattice. The origin would be the local appearance of quadratic domains, with a local antiferroelectric atrangement, as suggested by the low Kirkwood dielectric correlation factor (Amoureux et al 1984). An analysis of the steric hindrance in such domains, with a local antiferroelectric atrangement, as suggested by the low Kirkwood dielectric correlation factor (Amoureux et al 1984). An analysis of the steric hindrance in such domains reveals that among the configurations a priori possible, the local dielectric correlation factor (Amoureux et al 1984). An analysis of the steric hindrance in such domains reveals that among the configurations a priori possible, the local molecule is strongly correlated with that of its neighbours. All these arguments support the hypothesis of a distribution of correlation times. To describe the broadening of the molecule is strongly correlated with that of its neighbours. All these arguments used the hypothesis of a distribution of correlation times. To describe the broadening of the molecule is strongly correlation times have to be included in the scattering function, the hypothesis of a distribution of correlation times in the scattering function, weighting the related lorentian function with a distribution function G(t, t, ) according weighting the related lorentian function with a distribution function G(t, t, ) according

$$S_{inc}^{D}(Q, w) = a_{0}(Q)\delta(w) + \sum_{n=1}^{\delta} a_{n}(Q)\int_{w}^{w} \frac{1}{n!} \frac{1}{1+w^{2}r^{2}}G(r, r_{n}) dr \qquad (9)$$

In fact, this expression provides a theoretical and experimental ErsF identical to that given by (1), as long as the instrument resolution has not been taken into account, i.e. while it is much narrower than the experimental broadening, and can be considered as a

Figure 5. A sketch of the evolution of the distribution of the correlation times as a function of the temperature. Several instrument limits are indicated. Characteristic times fonger than these limits contribute to the clastic intensity.

Dirac o-function. Actually, the instrument resolution is finite. When the temperature is lowered, the motions are slowed down. The widths of the lotentzian functions related to longer correlation times progressively go outside the measurable energy range and the corresponding scattered intensity appears to be elastic (figure 5). This explains the increase of the apparent experimental EISF when the temperature decreases.

Without taking into account this probable correlation time distribution, an average relaxation time can be deduced from the spectra, by refinement of the twelve-jump model, providing that the purely clastic intensity is allowed to vary from the value predicted by the model. The resulting value,  $r_{mix} = 6 \times 10^{-10}$  s is of the order of magnitude of the value extrapolated from the Arthenius law for the plastic phase (Bee et al nitude of the value extrapolated from the Arthenius law for the plastic phase (Bee et al nitude of the value extrapolated from the Arthenius law for the plastic phase (Bee et al nitude of the value extrapolated from the Arthenius law for the plastic phase (Bee et al nitude of the value extrapolated from the Arthenius law for the plastic phase of the unit the plastic-glassy phase transition is of only little influence on the unitation is of only little influence of the unitation.

In order to demonstrate the effect of a distribution of relaxation times on the shape of the scattering spectrum, a simulation of the experimental spectra was performed. The distribution function  $G(r, r_i)$  was arbitrarily chosen as that introduced by Fuoss-Kirkwood (Connor 1964):

$$G(\mathbf{1}' \mathbf{1}') = \mathbf{U}(\mathbf{2}) = (\mathbf{h}/\mathbf{u}) \cos(\mathbf{h}\mathbf{u}/\mathbf{2}) \cosh(\mathbf{h}\mathbf{z}) / [\cos_3(\mathbf{h}\mathbf{u}/\mathbf{2}) + \sinh_3(\mathbf{h}\mathbf{z})]$$

:WG

with  $z = \log(r/r_i)$  where  $r_i$  is the correlation time corresponding to the maximum value of f(z). The  $\beta$ -parameter  $(0 < \beta \le 1)$  is equal to one for non-distributed relaxation times. Using equation (9), an analytical expression can be obtained for the scattering

$$S^{D}(Q, \omega) = a_{0}(Q)\delta(\omega) + \int_{\omega}^{A} a_{0}(Q) a_{0} \sum_{i=1}^{A} a_{i}(Q) a_{0} \sum_{i=1}^{A} a_{i}(Q) a_{0} \sum_{i=1}^{A} a_{0}(Q) a_{0}(Q) a_{0} \sum_{i=1}^{A} a_{0}(Q) a_{0}(Q) a_{0} \sum_{i=1}^{A} a_{0}(Q) a_{0}(Q) a_{0} \sum_{i=1}^{A} a_{0}(Q) a_{0}(Q$$

The simulated experimental spectrum  $S_{eq}^0$  is calculated from the convolution of  $S_e^0(Q,\omega)$  which the instrumentation of notion of  $S_e^0(Q,\omega)$  with the instrument notation function.

 $(\mathbf{n})$ 

(01)

346 M Bée et al

gaussian function:

$$S_{\text{trp}}^{\text{D}} = \frac{1}{\alpha(2\pi)^{1/2}} \left[ a_{\text{u}}(Q) \exp \frac{-\omega^2}{2\alpha^2} + \frac{1}{\pi} \sum_{i=1}^{6} a_i(Q) \beta \right]$$
$$\times \int_{-\infty}^{+\infty} \frac{1}{\omega'} \frac{(\omega'\tau_i)^{\beta}}{1 + (\omega'\tau_i)^{2\beta}} \exp \left( \frac{-(\omega - \omega')^2}{2\alpha^2} \right) d\omega' \right]$$

(12)

with  $\alpha = 0.425 \ \Delta \omega_{s}$ . Because of the divergence at  $\omega' = 0$ , in the domain  $[-\epsilon, +\epsilon]$   $(\epsilon \rightarrow 0)$ , this integral was approximated to be

$$2 \exp(-\omega^2/2\alpha^2) r_{\theta}^{\beta}(\varepsilon^{\beta}/\beta - \varepsilon^{\beta\beta} r_{\theta}^{\beta}/3$$

ŝ

The width of the gaussian resolution function (denoted  $\Delta \omega_{\rm f}$ ) was set to 1  $\mu$ eV, close to the experimental value. All calculations were performed on the basis of the twelvejump model. The spectra with and without distribution (denoted  $S_{\rm exp}^0$ ,  $S_{\rm exp}^0$ ) were calculated for Q = 1.5 Å⁻¹ and  $2/r_1 = \Delta \omega_1 = 3.2 \,\mu$ eV.  $\Delta \omega_1$  is the width of the narrower forentzian function contributing to the quasi-elastic scattering for the non-distributed spectrum. The  $\beta$ -parameter of the Fuoss-Kirkwood function was set to 0.6. In all cases (distributed or not), the total scattered intensity and the EisF values are constant. The resulting spectra are shown in figure 6. The quasi-elastic contributions are shown as

Clearly, from figure 6, there are noticeable differences between the spectra  $S_{\rm ep}^{\rm c}(Q,\omega)$  and  $S_{\rm exb}^{\rm col}(Q,\omega)$ .

Figure 6. Distributed 50, and non-distributed, 50, spectra (broken curves show the quasiclastic contributions).

The amplitude at  $\hbar\omega = 0$  is much more important in the case of the distributed spectrum (i.e.  $S_{ep}^{ep}(Q, 0)/S_{ep}^{ND}(Q, 0) = 1.26$ ). Furthermore, the broadening at halfmaximum of the quasi-clastic part for the distributed spectrum is about half that for the non-distributed one. Thus, assuming a single residence time, a *graphical* evaluation of the broadening leads to an overestimation of  $r_1$ . To go one step further, the distributed spectrum  $S_{ep}^{D}(Q, \omega)$  was classically *refined*, according to a single residence time  $r_{m_1}$ , (a pure locentzian function).  $\Delta\omega_1$  and a scale factor could be varied during the refinement. (The latter parameter has to be refined when considering real evperimental data.) The finement is of bad quality and leads to the final value  $\Delta\omega_1 = 3.35 \,\mu eV$ . Simultaneously

the scale factor was found to be much smaller (0.69) than for a non-distributed spectrum (1.0).

The simulated (distributed) spectrum and the corresponding refined one,  $S_{iap}^{NQ}$ , are illustrated in figure 7. This refinement procedure enables us to take into account the excess of the elastic amplitude, at  $\hbar\omega = 0$ , introduced by the distribution:  $S_{iap}^{Q}(Q, 0)/S_{id}^{NP}(Q, 0) = 2$ , which corroborates the experimental results. Nevertheless, the refined value of  $2/r_i$  (3.35 eV) is in good agreement with that introduced in the calculation of the distributed spectrum (3.2  $\mu$ eV).

Figure 7. Simulated S2, and corresponding S4. refined spectra (S4. is shown as the broken curve).

The refinement seems to favour the quasi-elastic contribution rather than the elastic one. This may be related to the low EISF value (for  $Q = 1.5 \ A^{-1}$ ,  $a_0(Q) = 0.149$ ) and to the relatively large quasi-elastic broadening compared with the instrument resolution  $(\Delta \omega_1 / \Delta \omega_n = 3.2)$ .

Keeping a constant instrumental resolution width of  $1 \mu eV$ , distributed spectra were calculated with decreasing values of  $\Delta \omega_1$ . The refinements lead to an increasing deviation, the final and expected values being only in good agreement for sufficiently fast motions, as  $\Delta \omega_1 = 2/\tau_1 > 3\Delta \omega_2$ . Moreover refinements with pure forentzian functions always yield an overestimated EISF value, and the choice of the appropriate model describing the molecular dynamics becomes difficult. When dealing with the interpretation of experimental data, it is clear that the more the temperature is lowered, the more the distribution widens (the  $\beta$ -parameter decreases) the longer the mean residence time becomes. Physical considerations, detailed above, suggest a description of the molecular motion of the twelve-jump model. but the mean residence time becomes. Physical considerations detailed above, suggest a description of the molecular motion of the twelve-jump model. but the mean residence time, deduced from the refinement of the real data using a non-distribution taket.

348 M Bée et al

To determine r₁, more accurately, one might envisage performing experiments with better instrument resolution, at least three times smaller than the phenomena being analysed. Unfortunately, this was not possible with the IN10 instrument as regards the investigation of the 'glassy' phase of ADM-CN.

The question arises of whether this distribution of molecular relaxation times also exists for the plastic phase. IONS experiments have been carried out using the fourchopper time-of-flight spectrometer INS at the Institut Lauc-Langevin (Bée *et al* 1980). For the lowest temperatures investigated, the broadening of the quasi-elastic contribution was about two times larger than the instrument resolution. The eventual distribution, in this plastic phase, will be much narrower ( $\beta \rightarrow 1.0$ ) than that in the glassy phase, the molecular motions being more free. From the above discussion, it is conceivable that the existence of this distribution might not be revealed. New experiments using INS, where the resolution can be easily varied, at the same incoherent energy, should provide precise information on this point.

## 5. Conclusion

The molecular reorientations of ADM-GN in its glassy phase cunnot be correctly described by a model involving a unique relaxation time. As suggested by conclusions of other experimental techniques, an interpretation in terms of a distribution of the relaxation times seems more appropriate. It is also demonstrated that no drastic change occurs at  $T_{\rm s}$  as regards the uniaxial rotation of the molecule.

## ABSTRACT

In the glassy-state of 1-cyanoadamantane obtained by rapid quenching from the plastic phase, the rate of the reorientations is not unique but widely distributed because the local order which varies from one molecule to another has been frozen. This distribution still exists in the plastic phase, even if the local order is partly averaged by the slow tumbling motion. Similar effects were recently observed with mixed crystals  $(C_{10}H_{15}CR)_x(C_{10}H_{15}Cl)_{-x}$ .

## INTRODUCTION

The existence of a new type of glasses, obtained by quenching of some molecular crystals initially in their orientationally disordered phase was evidenced by Adachi et al (Ref. 1). The normal transition into an ordered low-temperature phase is avoided and the specimen passes into a "glassy state", in which the average translational order of the plastic phase is preserved, but where the orientational disorder is frozen (at

least partially). This type of glasstransition has been observed with the 1-cyanoadamantane C10H15CN. The molecule has the general shape of a spherical adamantyl cage, on which is bonded the elongated radical C  $\equiv$  N (see Fig. 1). By rapid quenching, the normal transition  $\{T_t = 280 \text{ K}\}$  to the ordered monoclinic phase is avoided and the sample passes at  $T_{\alpha} = 170$  K into a glassy-crystal phase with the same averaged f.c.c. structure as the plastic phase (Fm3m, Z = 4). This latter has been largely described (Refs.2,3) and also the nature of the dynamical disorder.

Fig. 1 A possible configuration of 1-cyanoadamantane molecules with an antiferroelectric arrangement.

ANNEXE A = XI - 6

NMR, dielectric relaxation and Incoherent Quasielastic Neutron Scattering (IQNS) experiments have evidenced the simultaneous occurrence of two types of motions (Refs. 4-7) : i) reorientations of the molecule threefold-axis (dipole-axis) amongst <100> lattice directions, strongly hindered by the first and second neighbouring molecules and ii) a rotation of the molecule about this axis, much less hindered and described as 30° jumps over a circle.

Below T = 280 K, the crystal structure is monoclinic  $C_{2/m}$ , formed by a succession of parallel planes composed of molecules with their dipoles in antiparallel order (Ref. 8). In spite of a strong steric hindrance, the uniaxial rotation is still existing in that phase (Ref. 5). In the glassy phase ( $T_g = 170$  K), the molecules occupy the same equilibrium positions as in the plastic phase (Ref. 9). X-ray and coherent neutron scattering evidenced the progressive apparition of interlocked antiferroelectric domains (Refs. 10,11). Whilst the dipole tumbling is frozen at  $T_g$  (Ref. 12), the uniaxial rotation still continues to be observed by NMR (Refs. 5,8).

## HIGH-RESOLUTION IQHS IN THE GLASSY-PHASE

The experiments have been carried out at the Institut Laue-Langevin, in Grenoble. The backscattering spectrometer INIO was chosen because of its highresolution in energy, (c.a. 1  $\mu$ eV) on the expected relevant range (typically ± 13  $\mu$ eV). The flat specimen, 38 x 35 x 0.3 mm in size (transmission 0.9) was oriented at 45° of the incoming neutrons. Quenching was realised by directly dipping the sample into liquid nitrogen and then slowly heating up to the required temperature.

Fig. 2. Experimental ELSF values compared to jump-models over 3, 4 or 12 sites.

Fig. 3. Direct determination of the characteristic times from the experimental data. Experimental values of the Elastic Incoherent Structure Factor (EISF) were obtained from the ratio of the purely elastic scattered intensity over the wholespectrum intensity. They were compared with the values predicted by the models based upon reorientations over 3, 4 or 12 sites on a circle. It turns out that experimental values definitely lie above the predicted one, even for the 3-site model, in spite of its large amount of elastic scattering (see Fig. 2).

By Fourier-transformation, the scattering function was deconvoluted from the instrument resolution and the intermediate scattering function was obtained. A logarithmic plot as a function of time does not exhibit a simple linear decrease and thus proves that the motion cannot be described by any model involving a single exponential term (i.e. N = 2 or 3) (see Fig. 3). Moreover, at least two straight lines with distinct slopes in the ratio 1:5 can be observed, thus ruling out the N = 4 model predicting a ratio 1:2. Finally, the N = 12 model can also be eliminated, the ratio 1:5 being constant with 0.

An interpretation was proposed, strengthened by the results of other experimental techniques. X-ray and coherent neutron scattering evidenced the progressive occurrence of antiferroelectric domains. Thus, the immediate surrounding can differ from one molecule to another, with a net influence on their dynamics. The shape of the spectra should rather be analysed in terms of a distribution of the relaxation times and taking into account the instrument resolution. When the

## TIME-OF-FLIGHT IQNS IN THE PLASTIC PHASE

## Cyanoadamantane

The question arises if this distribution of molecular relaxation times also exists in the plastic phase. Earlier time-of-flight experiments (Ref. 7) exhibited at T = 300 K a small deviation of the EISF, in the range  $1.1 \text{ Å}^{-1} < q < 1.4 \text{ Å}^{-1}$  with respect to the 12-site model, the experimental values being above the theoretical curve. Recent experiments carried out over a large Q-range, with

several instrument-resolutions, definitely confirm this discrepancy. The EISF is found dependent on both the temperature and the resolution (see Fig. 5). This behaviour can be interpreted by a distribution of the relaxation times related to the progressive occurrence. when the temperature decreases, of clusters with local arrangement of the molecules. However, because of the slow tumbling reorientation of the molecule dipole moments, it is reasonable to consider that the distribution is more sharply peaked than in the glassy state. As soon as the temperature increases above room-temperature, most of the reorientations occur on the instrument time-scale. Near the melting point ( $T_m = 460$  K), nearly all of them occur with a unique correlation time.

## Cyanoadamantane/chloroadamantane alloys

Owing to their similarities,  $C_{10}H_{15}CN$  and  $C_{10}H_{15}Cl$  can crystallise together to form mixed crystals  $(C_{10}H_{15}CN)_x(C_{10}H_{15}Cl)_{1-x}$ . Both molecules have the same equilibrium orientations along 001 directions of f.c.c. lattice with similar parameters. They undergo the same type of reorientations but, while the frequency of the uniaxial rotation is nearly the same, the tumbling for  $C_{10}H_{15}Cl$  occurs at a much faster rate (10⁹ Hz) than for  $C_{10}H_{15}CN$  (10⁴ Hz at T = 250 K). Calorimetric measurements (DSC), NMR or dielectric relaxation, X-ray structure determinations clearly indicate that dynamics of these mixed crystals tend to that of cyanoadamantane, i.e. a quasi-static disorder of the orientations of the molecule dipole-axes, for x + 1. Conversely, for x + 0, the behaviour is similar to that of chloroadamantane, i.e. we are concerned with a dynamical disorder of the dipoles. IQNS experiments were carried out with a series of mixed crystals with intermediate concentrations, x = 0.20, 0.33 and 0.67. In order to analyse more precisely the dynamical behaviour of each species, measurements were also performed with partially deuterated samples  $(C_{10}H_{15}CN)_{x}(C_{10}D_{15}CI)_{1-x}$ .

Fig. 5 Experimental EISF values

instrument resolutions.

20

Experimental EISF values were found strongly temperature-dependent, as illustrated in Fig. 6 for the fully hydrogenated species x = 0.33. At each temperature, the curve is intermediate between the curves for pure species x = 0 and x = 1, but, it never corresponds to their simple weighted average. That proves

Fig. 7. Scattered intensity versus Q and Guinier plot for the two partially deuterated mixed crystals at T = 300 K.

T-300 K

1 CN/CIII/DI 1/2

2 O/Å'

4 01/2.1

that we are actually concerned with a molecular mixture of the two species.

The partially-deuterated specimen gives rise to a strong coherent scattering (see Fig. 7), especially at smaller 0-values. After subtracting the incoherent part, the amount of coherent scattering is found proportional to the concentration of C10D15Cl. A Guinier plot yields a radius of about 2.6 A which corresponds to the radius of one individual molecule.

s-(0)

) <u>5</u>] 8a-

ŝ

The coherent scattering was proved to be elastic in nature. After correction for its contribution to the scattered intensity, the experimental values of the EISF are found similar for hydrogenated and partially deuterated specimen. Clearly, there is no difference in the dynamics of  $C_{10}D_{15}Cl$  and  $C_{10}H_{15}Cl$ , for the same concentration (Fig. 8).

The mixed crystal corresponding to x = 0.20 is found to have a behaviour very similar to pure chloroadamantane, and the variation with temperature of the EISF for x = 0.66 tends to be close to that for pure cyanoadamantane. The specimen for x = 0.33 exhibits a stronger temperature dependence, which is likely related to the thermal activation of the tumbling of the chloroadamantane molecules in it.

## **CONCLUSION**

The exact nature of the local ordering has yet to be elucidated. New experiments are planned in order to get some insight on the molecular arrangement on

## ABSTRACT

The structures of different phases of chloroadamantans, browoadamantane iodoadamantane and cysnoadamantane have been measured by X-ray diffraction.

The physical nature of the order parameters implied by the symmetry reduction is established for the observed phase transition. A model is proposed for description of phase transitins in cyanoadamantane on the basis of thermal variation of strains in its low temperature phase.

## INTRODUCTION

Except for iodoadamantane (1-ADM) the derivatives of adamantane  $C_{10}H_{15}X$ (called below X-ADM) have their highest temperature solid plastic phases caracterized by the space group FmJm (2 = 4).

The low temperatures phases of these substances exhibit a variety of structures with different degrees of molecular order according as the substituting element K changes. The existence of relationships between the high and low temperature lattices allows to establish formal structural order parameters that gives indications on the transition mechanism.

## SOLID PHASES OF SOME DERIVATIVES OF ADAMANTANE

Hain results of X-ray diffraction investigations of Cl-ADH, Br-ADH, CN-ADH and I-ADH are presented in Table I along with the phase transition temperatures. The ordering of molecular dipoles in the phases investigated are schematised in Fig. 1.

The phase transitions P = 0 in all substances and P = 50 in Br-ADM are strongly discontinuous and end up with powdering of crystals. The glassy phase G of CN-ADM is got only by a rapid quenching of the plastic phase (ref.1). The dipoles order shown in fig. Ic has a local nature the extent of corresponding domains being of the dimension 40Å (ref. 2).

GROUP THEORETICAL DESCRIPTION OF DIPOLES ORDERING IN Br-ADM and C1-ADM

The reduction of symmetry for the phase transitions P + SO in Br-ADH ; P + O in Cl-ADM and SO + O in Br-ADM read respectively

Fin 3m + 
$$(k_4 = (\gamma n/a, \gamma n/a, 0); \gamma = 1, \tau^3, n_1 = n_2 = n) + Pmcn$$
 (1)  
Fm 3m +  $(k_4, \gamma = 1, \tau^3, \tau^2; n_1 = n_2, \zeta_1 = \zeta_2 = \zeta_1 + P_2 / c$  (2)  
Pmcn +  $(k_9 = 0, \tau^2 = B_{2g}) + P_2 / c$  (3)

Notation of irreducible representations  $(k_i, \tau^n)$  after ref 4.

 $\eta_i$  and  $\zeta_i$  are the components of the real physically irreducible representations engendered by the loaded ones  $\tau^3$ , and  $\tau^2$  respectively.

The phase transition SO  $\rightarrow$  O is close to second order in accordance with one dimensional active representation.

The physical quantities fluctuations compatible with the representations involved in (1) and (2) are exhibited in Tig 2. The corresponding order of molecules is not complete.

Thus, one introduces an additional order parameter defined by symmetry reduction scheme

Fm3in +  $(k_{10} = (0,0,2 \pi/a) \tau^{10}, \upsilon_1 = \upsilon_2 = \upsilon) + Pman \Rightarrow Pmcn (4)$ 

Such a change of order is always discontinous because of the existence of Lifshitz invariant in the representations  $(k_4, \tau^1)$ . An alternative possibility of the instability in  $\eta$  being triggered by the one in  $\upsilon$  also leads to a discontinuity. A strong coupling with strain (volume contraction 5.4°/. in Cl-ADH) makes the transitions destructives.

### MODEL FOR PHASE TRANSITIONS IN CN-ADH

The sequence of phases in CN-ADM is shown Fig.3. The symmetry reduction leading to the tetragonal structure of annealled phase G reads Fm3m + ( $k_{10}$ ,  $\tau^{*}$ ,  $\upsilon \neq 0$ )  $\rightarrow$  P4/nmm (5)

The one domain crystal of the tetragonal symmetry is never observed because of limited molecular mobility. Than the glassy phase G is represented as a composition of different tetragonal domaines of symmetry P4/nmm.

The possible symmetry reduction in phase transition  $P \rightarrow 0$  are following  $Fm \exists m \rightarrow (k_g = (\pi/a, \pi/a, \pi/a), \tau^6, \eta \neq 0) \rightarrow C2/m$  (6)  $Fm \exists m \rightarrow (k_g = \tau, ^2 \rho = 0) \rightarrow R \exists m \rightarrow (k = 0, Eg) C2/m$  (7)

The order parameter  $\rho$  governs the molecules' orientations whereas the one A the displacements of their mass centres. With the strain components defined as  $\alpha = (\epsilon_1 + \epsilon_2^{-2}\epsilon_3)/6$ 

Fig. 2

Fig. 4

- Fig. 2 Projection of orientational distribution in phase  $t^{\prime}$  (a) translationed ( $f^{\prime}$ ) and orientational ( $f^{\prime}$ ) displacements of symmetry ( $k_{i}$ ,  $\tau^{1}$ ) (b) orientational probability fluctuations of symmetry ( $k_{i}$ ,  $\tau^{1}$ ) (c) and ( $k_{10}^{\prime}$ ,  $\tau^{14}$ ) (d). Effective orientatioal order parameter (e)
- Fig.] Scheme of free energies of CN-ADH in its different phases. Q-Quenched A-annealed glassy state.
- Fig. 4 Temperature dependence of spontaneous strain componence in phase 0 of CN-ADH. Dashed line cheoretical curve implied by  $K = K_0 + K_1$  (T-To) in (9)

$$\delta = (\varepsilon_1 + \varepsilon_2 + \varepsilon_3)/3, \ \beta = (\varepsilon_4 + \varepsilon_5 + \varepsilon_6)/3 \quad \gamma = (2\varepsilon_6 - \varepsilon_5 - \varepsilon_4)/6$$

The simplest free energy expansion in phase O reads

$$F = (a_{p}/2)\rho^{2} + (b_{p}/4)\rho^{4} + (a_{n}/2)n^{2} + (b_{n}/4)n^{4} + (d_{n}/6)n^{6} + (C_{1}/2)u^{2} + (C_{2}/2)B^{2}$$

 $-(K/2) \eta^2 \rho^2 - L u \eta^2 - M \beta \rho^2 - N \beta \eta^2$ 

The lack of pretransitional effects in phase P implies that  $a_{ij}$ ,  $a_{ij}$ ,  $C_1$ and  $C_2$  are constants with temperature Assuming almost perfect order of the  $\frac{1}{2}$  poles in phase 0 different possibilites of linear thermal dependence of the expansion (9) coefficients have been examined to get the best fit with experimental variation of the  $\alpha$  component of spontaneous strain. This procedure indicated the coefficient K = K + K₁T as the most temperature dependent in the vicinity of phase transition (Fig. 4). Thus the phase transition P = 0 is attributed to the thermal dependence of orientation-translation coupling coefficient (réf. 5)

## TABLEAU XII-8

Le temps de résidence affiné,  $\tau_{m12} \times 10^{13}$ s, pour des concentrations et des températures différentes (modèle d'ordre 12 sans tenir compte des distributions)

différents traitements thermiques subis par le cristal :

- a) vieillissement à 157K pendant 70 heures
- b) réchauffage : réversion vers 180K
- c) vieillissement à 180K pendant 3 heures

d) réchauffage : transition III - I vers 237K.

Température de recuit	Demi large 121 juste réchauffag	eur du profil avant le je (u.r.r.)	Taille des domaines (Å)	Température du début de la réversion
157K		0.115	35	179К
168K		0.09	48	186K
170K	*	0.08	54	190K
176K	*	0.07	62	193K
180K	*	0.05	86	pas de réversion mais transition à 237K

#### TABLEAU XII-9 extrait de [2]

" : cristal pour lequel nous avons noté une saturation

- La vitesse de réchauffage a toujours été de l'ordre de 6K/minute
